ABSTRACT

This research aims to investigate the possibility of electrospun fibers from Polymers of Intrinsic Microporosity (PIM-1) as an alternative adsorbent for aniline removal from both air and aqueous solution. Adsorption properties of electrospun PIM-1 fibers were compared with powder and film form of PIM-1. While electrospun PIM-1 nanofibrous mat can adsorb 871 mg g⁻¹ aniline from air, it can also adsorb 78 ± 5.4 mg g⁻¹ aniline from aqueous environment when 50 mg L⁻¹ aniline solution is used. The experimental maximum adsorption capacity of electrospun PIM-1 fibers was found as (qₑ) 138 mg g⁻¹. Langmuir and Freundlich isotherm models have been studied and Langmuir model found more appropriate for aniline adsorption on electrospun PIM-1 fibers. The study reveals that self-standing electrospun fibrous mat of PIM-1 has shown potential to be used as an efficient adsorbent material for the adsorption of VOCs from air and aqueous system thanks to its fast kinetic and high adsorption capacity.

1. Introduction

Air and water pollutions are major problems faced by today's world. The situation is further aggravated by industrialization as the pollutants released into environment without proper treatment methods [1,2]. Aniline is an important organic compound that is widely used as an intermediate in the production of pharmaceuticals, dyes and pesticides [3,4]. Aniline is a common volatile
organic compound (VOC) that can contaminate both air and aquatic environment [5]. The presence of aniline may cause serious environmental and health problems because of its toxicity [6,7]. Hence, removal of aniline from air and water has attracted serious attention from researchers. A number of processes including oxidation [8], biodegradation [9], membrane separation [10], adsorption [11] and some other processes can be applied for removal of aniline [12]. From the technical and economical points of view, adsorption is regarded as one of the most promising method for aniline removal [13].

Recently, Polymers of intrinsic microporosity (PIMs), a new class of polymer, attracted significant interest due to their unusual structural feature with a backbone composed of fused rings and site of contortion [14,15]. PIMs behave as molecular sieves and show high free volume as they cannot pack space efficiently [16]. PIMs have attracted widespread attention as material for sensor [17,18], catalysis [19,20], membrane separation [21,22], adsorbents [23] and other applications. Although a number of PIMs have been synthesized, the first member of this class, PIM-1, received the main focus as it shows great separation performance in the gas separation [24,25]. PIM-1, has high surface area, high thermal and chemical stability and, is soluble in common organic solvents such as tetrahydrofuran and chloroform, and can be processed in the forms of powders, membranes and fibers. PIM-1 is an organophilic polymer that is selective towards organic compounds and it shows extremely high CO₂ permeability along with moderate selectivity in the membrane form. Moreover, PIM-1 membranes employed successfully in pervaporation systems to separate VOCs from aqueous system as the system has the same mass transfer mechanism with the gas separation system [26,27]. It was also studied in organic solvent nanofiltration system [28]. Recently, comparative study has been conducted by using high free volume polymer including PIM-1, poly(1-trimethylsilyl-1-propyne) (PTMSP) and poly(4-methyl-2-pentene) (PMP). PIM-1 showed great sorption selectivity along with sorption ability for neutral dye (Solvent 35) in ethanolic solution compared to other polymer [29]. Later on, the possibility of using PIM-1 as an adsorbent and membrane material was investigated using combined process of solvent swing adsorption with solvent recovery by nanofiltration [30]. In addition to membrane form, PIM-1 has also been produced in the form of hollow fibers showing similar performances in gas separation [31,32]. The fiber form can also be produced by electrospinning method which is fairly simple and versatile way to produce three-dimensional porous adsorbents for various applications [33–39]. Electrospinning of PIM-1 is a fairly new concept that was investigated recently [40–43]. Bonso et al. [40] was first used tetrachloroethane solution to produce electros spun PIM-1 fiber mat. Following this, PIM-1 mat was carbonized and used successfully as an electrode for supercapacitors. Then, the preparation of PIM/POSS fibrous membranes were developed and their oil/water separation performances have been studied by Zhang et al. [42]. The same group also have investigated the adsorption of dyes from non-aqueous media by electros spun PIM-1 [41]. Lassegquette et al. [43] employed different solvent system for the fabrication of electros spun PIM-1 by using tetrahydrofuran/dimethylformamide mixture.

In this study, we have prepared electros spun PIM-1 fiber and the aniline removal ability of electros spun PIM-1 was compared with powder and film form of PIM-1 from air and water. The study revealed that all forms of PIM-1 have the ability to adsorb aniline from air within 24 h. Moreover, PIM-1 fiber shows considerable aniline adsorption from aqueous system up to 138 mg g⁻¹ (qₑ). While powder and fiber forms of PIM-1 show higher adsorption capacity than film form, fiber form of PIM-1 found more applicable in aqueous system as powder form dispersed in water and it needs additional filtration for analysis. On the other hand, fiber PIM-1 shows better stability and it maintains the fiber morphology that provides practical advantage in adsorption and reuse of adsorbent.

2. Experimental
2.1. Materials

5,5',6,6'-Tetrahydroxy-3,3',3'-tetramethyl-1,1'-spirobisindane (TTSBI, 98%, Alfa Aesar) was dissolved in methanol and re-precipitated from dichloromethane before use. Tetrafluoroterephthalonitrile (TFTN, 98%, Aldrich) was purified by sublimation: pure product collected without vacuum. Anhydrous potassium carbonate (K₂CO₃, 99.0%, Fisher) was dried in an oven at 110 °C overnight before use. Dimethylacetamide (DMAc), toluene, dimethylfor- mamide (DMF), methanol (MeOH), chloroform (CHCl₃), tetrahydrofuran (THF), dichloromethane (DCM) and 1,1,2,2-tetrachloroethane (% 98) were purchased from Sigma Aldrich and were used as received.

2.2. Synthesis of PIM-1

Synthesis of PIM-1 was performed as reported previously [44]. Yield: 62 g (90%). GPC: Mₓ = 106,000, M₀ = 189 000, Mₓ/M₀ = 1.78. 1H NMR (400 MHz, CDCl₃, d, ppm): 6.75 (2H, s), 6.35 (2H, s), 2.26–2.09 (4H, dd), 1.40–1.10 (broad, 12H). ATR-IR (cm⁻¹): 2995, 2864, 2239, 1605, 1446, 1264. Anal. calcd for C₂₉H₂₀N₂O₄ (wt%): C: 75.64, H: 4.37, N: 6.08 found: C: 74.6, H: 4.4, N: 5.9.

2.3. Film preparations

PIM-1 (0.2 g) was dissolved in CHCl₃ (8 mL) and stirred overnight to ensure a homogenous casting solution. The casting solution was filtered through glass wool into a glass dish. The cast solution was covered by glass funnel and left for 48 h to allow solvent evaporation. The freshly formed film was removed from the glass dish with the help of an ethanol/water mixture (1:1). Then it was dried in an oven at 110 °C overnight.

2.4. Electrospinning

PIM-1 powder was dissolved in 1,1,2,2-tetrachloroethane at the concentration of 23% (w/v). The PIM-1 solution was stirred at 60 °C for 1 h and left stirring overnight at room temperature and degassed for 15 min prior to use. Following that, about 2 mL of the PIM-1 solution was placed in a 3 mL syringe, which was equipped with a blunt metal needle with an inner diameter of 0.5 mm and the syringe was positioned horizontally on the syringe pump (Kp Scientific, KDS 101). Metal plate collector was covered by an aluminum foil then placed across the syringe to collect microfibers. Extensive optimization studies have been performed for the electrospinning and the applied parameters were as: flow rate of the polymer solution; 0.5 mL h⁻¹, applied voltage; 11–12 kV and tip to collector distance; 18 cm, rotation speed of the collector; 2000 rpm. Then, the collected fibers were detached from the aluminum surface by spraying MeOH on fiber surface to ease the stress on fibers and inhibit the immediate stretching. Finally, the PIM-1 fiber was dried in an oven at 130 °C under vacuum for overnight.

2.5. Methods

The molecular weight of PIM-1 was measured by an Agilent gel-permeation chromatograph (GPC) equipped with a ZORBAX PSM 300-S column, which was calibrated using polystyrene standard samples-THF was used as mobile phase at a flow rate of 1 mg
mL⁻¹. Infrared (IR) spectra of samples were recorded on a Bruker Vertex 70 spectrometer. Samples were mixed with potassium bromide (KBr) and pressed under the pressure of 8 tons to prepare pellets. Each sample was scanned 64 times at a resolution of 4 cm⁻¹. Peak areas were calculated using Omnic software. ¹H nuclear magnetic resonance (¹H NMR) spectra was collected using a Bruker DPX-400 MHz spectrometer at room temperature. Polymer solutions were prepared in CDCl₃. Chemical shifts were referenced to tetramethylsilane (TMS). Thermo Scientific Flash 2000 series CHNS-O analyzer was used for elemental analysis. 2,5-(bis[5-tert-butyl-2-benzoxazol-2-yl])thiophene was used as a standard. Samples (1–1.5 mg) were mixed with vanadium pentoxide (8–10 mg) that was used as a catalyst for complete oxidation. N₂ adsorption isotherms at −196 °C were measured using a autosorb iQ gas sorption analyzer. A small amount of sample (~0.1 g) was weighed into an analysis tube and degassed under high vacuum at 120 °C for 960 min. Analysis was conducted after reweighing the degassed sample. Brunauer–Emmet–Teller (BET) surface areas were calculated from N₂ adsorption isotherms by multi-point analysis. Scanning electron microscopy (SEM) images were recorded using a FEI Quanta 200 FEG scanning electron microscope. After coating samples with 5 nm Au–Pt imaging and the analysis was performed at 10 kV. The diameters of electrospun fibers were quantified using ImageJ software by measuring about 100 different fibers. Thermo-gravimetric analyzer TGA Q500 (TA Instruments) was used to determine hysteresis on desorption that may point out polymer swelling. Each sample was scanned 64 times at a resolution of 4 cm⁻¹. ¹H NMR spectrum of PIM-1 is displayed in Fig. 1(b) showing four different proton environments. Thermal properties of PIM-1 are studied using thermogravimetric analysis technique that shows polymer is thermally stable and it starts degrading at 450 °C (Fig. 1c). This behavior explained as polymer backbone degradation.

2.6. Aniline adsorption from air

Powder, fiber and film forms of PIM-1 were used for trapping aniline. 1 mL of aniline was placed in 50 mL glass vial then adsorbents were placed in this vial and sealed with paraffilm. The samples kept for 24 h at room temperature to ensure maximum adsorption occurred. Then they were removed from glass vial and kept under suction hood for a certain period.

2.7. Aniline adsorption from aqueous system

For aniline adsorption studies, aqueous stock solution of aniline was prepared in deionized water. Different concentrations were prepared by dilution of the stock solution with deionized water. Calibration solutions were prepared from 200 to 16875 mg L⁻¹ and their absorbance were measured using an autosorb iQ gas sorption analyzer. A small amount of sample (~0.1 g) was weighed into an analysis tube and degassed under high vacuum at 120 °C for 960 min. Analysis was conducted after reweighing the degassed sample. Each sample was scanned 64 times at a resolution of 4 cm⁻¹. ¹H NMR spectrum of PIM-1 is displayed in Fig. 1(b) showing four different proton environments. The structure of and purity of PIM-1 were confirmed using FT-IR and ¹H NMR spectroscopy techniques [44]. FT-IR spectrum of PIM-1 is depicted in Fig. 1(a) which shows characteristic nitrile (CN) stretches at 2240 cm⁻¹ along with aromatic and aliphatic C–H stretches around 3000 cm⁻¹. ¹H NMR spectrum of PIM-1 is displayed in Fig. 1(b) showing four different proton environments. Thermal properties of PIM-1 are studied using thermogravimetric analysis technique that shows polymer is thermally stable and it starts degrading at 450 °C (Fig. 1c). This behavior explained as polymer backbone degradation.

3. Result and discussion

3.1. Structural characterization

Synthesis of PIM-1 has a long history and several methods have been introduced for PIM-1 preparation [15,45]. PIM-1 can be produced by using commercial monomers and as synthesized PIM-1 shows significant fluorescent yellow color. The PIM-1 used in this study has molecular weight (Mₘ) of 189 kDa and it shows narrow PDI of 1.78. The structure of and purity of PIM-1 were confirmed using FT-IR and ¹H NMR spectroscopy techniques [44]. FT-IR spectrum of PIM-1 is displayed in Fig. 1(b) showing four different proton environments. Thermal properties of PIM-1 are studied using thermogravimetric analysis technique that shows polymer is thermally stable and it starts degrading at 450 °C (Fig. 1c). This behavior explained as polymer backbone degradation.

3.2. Electrospinning of PIM-1 fibers

Previous studies have reported the preparation of bead-free electrospun PIM-1 fibers by using 7 to 10% polymer in tetra-chloroethane solutions with 127 and 292 kDa molecular weight of PIM-1 polymer [40–42]. In the present study, we have employed the PIM-1 with a molecular weight of 189 kDa (Mₘ) with a narrow PDI (1.78). However, we only managed to produce fibers with over 23% (w/v) polymer solution in the same solvent (tetra-chloroethane). Moreover, wetting, is observed when the electrospun fibers were collected on the rotating drum at 100 rpm as reported in previous studies [40–42]. This was overcome by increasing the rotation speed of drum collector to 2000 rpm which also enables the formation of completely dried solid fibers with aligned fiber morphology. Following the electrospinning, polymer sticks on the surface of the aluminum foil which makes difficult to detach the fibers from the surface without giving a physical damage. Thus, the sample was treated with methanol for a short period of time in order to avoid the physical damage, since PIM-1 swells reversibly in the presence of alcohol and it was dried afterwards [14,15,46]. Fig. 2(a) displays the digital image of fluorescent, self-standing fibrous electrospun PIM-1 and SEM images of bead-free, rounded and aligned PIM-1 fibers are shown in Fig. 2(b). The average fiber diameters were found 2.07 ± 0.52 μm for this polymer under the applied conditions and a relatively uniform fiber diameter distribution has been attained (Fig. 2c).

3.3. Aniline adsorption from air

PIM-1 has a high surface area, making it a promising candidate for adsorption studies. BET surface area measurements showed that PIM-1 powder and fiber have the same apparent surface area around 770 m² g⁻¹ and film form of PIM-1 has slightly lower surface area with 720 m² g⁻¹. All PIM-1 samples show type I isotherm at low pressure indicating significant microporosity. They also display hysteresis on desorption that may point out polymer swelling. N₂ adsorption/desorption isotherms and pore parameters data are provided in Supplementary information in Figs. S1–5 and Tables.
S1–5. It has been reported that PIM-1 has high affinity for organic species and effectively used for removal of organic contaminants [41,47]. Thus, we have investigated the adsorption of aniline from air by electrospun PIM-1 fibers and compare the results with powder and film form of it. $^1$H NMR and TGA were used effectively to quantify the amount of aniline trapped in the PIM-1 matrix. Fig. 3 exhibits the $^1$H NMR spectra of PIM-1 in CDCl$_3$ before and after aniline adsorption. It can be clearly seen that aniline adsorbed PIM-1 shows distinct aromatic protons between 6 and 8 ppm along with amine protons (–NH$_2$) at 3.7 ppm. Thus, the integration of amine signal of aniline and the aromatic proton of PIM-1(Ar-H$_4$) may assist to calculate the amount of aniline which is trapped in PIM-1. The aniline adsorption capacity of PIM-1s was found from $^1$H NMR based on Eq. S6 in Supplementary information. The highest uptakes were found 558, 774 and 871 mg g$^{-1}$ for powder, film and fiber PIM-1 respectively.

The adsorption of aniline by PIM-1 was also observed by TGA which indicates a great adsorption performance. Fig. 4 shows the TGA curves of film, powder and fiber form of PIM-1 before and after the adsorption. While powder and film form do not show any weight loss before 450 °C, electrospun fiber PIM-1 shows a slight weight loss (2%) between 120 and 190 °C due to the trace solvent content. Hence, solvent correction is applied for fiber PIM-1. The aniline adsorbed samples showing significant weight
Thus, the aniline adsorption capacity of PIM-1s was calculated. High uptakes were found 634, 779 and 818 mg g\(^{-1}\) for film, fiber and powder samples respectively from 50 mg L\(^{-1}\) aniline solutions (Fig. 5a). Even though powder PIM-1 can adsorb slightly higher amount of aniline, the separation of adsorbent from solution requires additional filtration step which makes difficult to continue and examine time profile of adsorption precisely. Thus, the adsorption was studied over the time for fiber and film PIM-1s. Fig. 5(b) exhibits that fiber PIM-1 can reach equilibrium within 5 h, although film PIM-1 requires much longer contact time (72 h) to reach the equilibrium. This was first considered by sample’s hydrophobicity, and contact angle measurement has showed 84 ± 2° for film and 134 ± 8° for fiber PIM-1. The results are in good agreement with previous studies. Digital images of water drops on PIM-1 film and fiber are provided in Supplementary information in Fig. S9. Then, the reason for such a slow kinetic was thought to be related to density of the PIM-1 samples. Film form is denser than fiber and powder form, thus, it may follow slower kinetic. The kinetic data were aimed to analyzed by pseudo-first-order and pseudo-second-order rate models. However, the data is not sufficient enough to distinguish the precise model. The results confirm the more rapid adsorption by fiber PIM-1. The kinetic data are supported in Supplementary information (Tables S6–7 and Figs. S10–11).

The adsorption capacity of adsorbents can be examined by the adsorption isotherms [49]. In order to examine the adsorption capacity of electrospun fiber PIM-1 with other materials, the isotherm experiments were conducted and experimental maximum adsorption capacity was found 138 mg g\(^{-1}\) for PIM-1 fiber (Fig. 5c and Table S8). Data was analyzed using Langmuir and Freundlich models as it displayed in Fig. S12. It was found that the Langmuir model is the best model for describing the adsorption of aniline on PIM-1 fiber as the adj. \(R^2\) of aniline is greater than that of Freundlich model, implying the adsorption follows monolayer coverage, and the surface is relatively homogeneous. Similar observation has been reported for orange II adsorption by PIM-1 powder from an aqueous system [50]. The constants of isotherm models are given in Supplementary information in Table S9 and theoretical maximum adsorption capacity was found as 161.2 mg g\(^{-1}\) which is slightly higher than experimental maximum adsorption capacity. In addition to fast kinetic, electrospun PIM-1 fibers are stable in water and the fiber morphology is kept after the adsorption. Moreover, regeneration of adsorbent has also been achieved by using acidic methanol treatment for a short period of time. SEM images of PIM-1 after 3 cycle of adsorption/desorption is provided in Supplementary information (Fig. S13). However, using acidic methanol solution to desorb the aniline that was adsorbed on PIM-1 surface was not found reliable in terms of quantification. As aniline protonated in acidic medium creating a decent calibration curve does not seem possible. Fig. S14 in Supplementary information displays the UV spectra of aniline obtained from acidic methanol solution for 370 ppm and 185 ppm concentration that limit to obtain specific absorption coefficient, \(a\), by simple calibration. For that reason, ethanol solution is used for desorption experiment as PIM-1 can swell reversibly in the presence of alcohol. The alcohol treatment method is widely used to remove residuals from PIM-1 structure in gas separation [51–53]. Thus, adsorbed aniline was desorbed into ethanol solution within 1 h. Note that, Value of \(\lambda_{max}\) for aniline in ethanol was found as 286 nm (Fig. S14), due to slight shift in \(\lambda_{max}\) value specific absorption coefficient was also recalculated for ethanol solution. Water and ethanol calibration curves are also provided in Supplementary information in Fig. S15. Regeneration of PIM-1 fiber and adsorption/desorption efficiency can be seen in Fig. 5d that shows PIM-1 fiber maintains 85% of its adsorption capacity after 4 cycles. Note that, PIM-1 is soluble in chloroform, thus, in the case of any significant reduction in adsorption capacity it can be dissolved in chloroform and re-precipitate from methanol. Following regeneration of polymer, fresh PIM-1 fiber can be obtained by electrospinning repeatedly until polymer plasticize. The value of \(q_m\) is compared with other adsorbents and it was higher than that

![Fig. 3. \(^1\)H NMR spectra of PIM-1 (solid line) and aniline adsorbed PIM-1 (dashed line) fibers in CDCl\(_3\).](image)

![Fig. 4. TGA curves of powder, film, and fiber, form of PIM-1 before and after aniline adsorption. Solid lines indicate samples before in contact with aniline and dashed lines indicate samples after in contact with aniline within 24 h.](image)
of many other adsorbents reported in the literature. Table 1 shows the comparison of the maximum adsorption capacities, surface areas and pore parameters of different adsorbents towards aniline under the applied conditions.

Note that, adsorption capacity of PIM-1 fiber from air is greater than that from water. Since in air adsorption experiment, the environment is mainly including aniline molecules so minimal interruption occurs for the interaction between PIM-1 and aniline molecules in the gas form. On the other hand, water inhibits the interaction between PIM-1 and aniline molecules in liquid form. As PIM-1 knows as hydrophobic polymer. Water contact angle of PIM-1 fiber is found 134 ± 8° (Fig. S9) that is possibly inhibits the proper interaction with aniline molecules in water. Moreover, the interaction between water-aniline molecules are possibly higher than the interaction between PIM-1-aniline molecules causing less adsorption from water but the material is still promising for an adsorption from mainstream not only as an air filter.

4. Conclusion

In this study we have prepared electrospun PIM-1 fibers in order to investigate the aniline adsorption ability and data was compared with powder and film form of PIM-1. All forms of PIM-1 show great adsorption performances for aniline adsorption. Maximum aniline adsorption capacities from air were found 558, 774

Fig. 5. (a) The amount of aniline adsorbed by different forms of PIM-1 in 50 mg L⁻¹ aniline solution. (b) kinetic curves of aniline adsorption by fiber and film PIM-1. (c) Adsorption isotherm of aniline on PIM-1 fiber. (d) Adsorption/desorption efficiency of fiber PIM-1 from water and ethanol solutions.
and 871 mg g⁻¹ for powder, film and fiber form of PIM-1. The aniline adsorption from aqueous solutions were also investigated. Electrosprun PIM-1 fibrous mat shows fairly fast adsorption within 5 h compare to PIM-1 film. The experimental maximum adsorption capacity (qₑ) of electrosprun PIM-1 fibrous mat was found as 138 mg g⁻¹, while theoretical maximum adsorption capacity (qₘ) was calculated as 161.2 mg g⁻¹ that surpasses most of the adsorbents reported in literature. Langmuir and Freundlich isotherm models have also been studied and Langmuir model found more appropriate for aniline adsorption on electrosprun PIM-1 fibers. The study demonstrated that electrosprun PIM-1 fibers can be a potential candidate for adsorptive removal of aniline both in air and aqueous media.
