Abstract

Fe(III) (oxyhydr)oxides are ubiquitous in modern soils and sediments, and their large surface area leads to scavenging of trace elements. Experimental trace element partitioning between Fe(III) (oxyhydr)oxides and aqueous solutions have been used to elucidate the geochemical composition of the Precambrian oceans based on the trace element concentrations in Precambrian banded iron formations (BIFs). However, previous partitioning experiments did not consider the potential influence of microbially-derived organic material, even though it is widely believed that bacterial phytoplankton was involved in Fe(II) oxidation and the deposition of BIF primary minerals. Therefore, the present study focuses on sorption of Ni to, and co-precipitation of Ni with, both biogenic ferrihydrite precipitated by the freshwater photoferrotroph \textit{Rhodobacter ferrooxidans} \textsuperscript{SW2} and the marine photoferrotroph \textit{Rhodovulum iodosum}, as well as chemically synthesized ferrihydrite. We considered the influence of cellular organic material, medium composition and the availability of dissolved silica. Our results show a preferential association of Ni with ferrihydrite, and not with the microbial cells or extracellular organic substances. We found that the addition of silica (2 mM) did not influence Ni partitioning but led to the encrustation of some cells with ferrihydrite and amorphous silica. The two- to threefold lower Ni/Fe ratio in biogenic as compared to abiogenic ferrihydrite is probably due to a competition between Ni and organic matter for sorption sites on the mineral surface. Additionally, the competition of ions present at high concentrations in marine medium for sorption sites led to decreased Ni sorption or co-precipitation. Based on our data we conclude that, if the Fe(III) minerals deposited in BIFs were – at least to some extent – biological, then the Ni concentrations in the early ocean would have been higher than previously suggested. This study shows the importance of considering the presence of microbial biomass and seawater ions in paleomarine reconstructions.

1. INTRODUCTION

Nickel (Ni) is incorporated into several specific Ni-dependent enzymes, such as NiFe-hydrogenases, carbon monoxide dehydrogenase, acetyl-CoA decarboxylase/synthase, methyl coenzyme M reductase and others (Mulrooney and Hausinger, 2003). Ni-enzymes are thought to have evolved early, as most of them are confined to anaerobic prokaryotes, such as methanogens, that were likely active on early Earth (e.g., Zerkle et al., 2005).

Estimates of trace metal bioavailability in Precambrian oceans may provide insights into the evolution of the biosphere based on the requirement of these metals by specific enzymes (e.g., Saito et al., 2003; Zerkle et al., 2005; Anbar, 2008; Robbins et al., 2013). The bioavailability of trace metals is tightly controlled by minerals such as Fe(III) (oxyhydr)oxides (Brown et al., 1998) due to their large reactive surface area and their high sorption affinity for metal cations (Cornell and Schwertmann, 2003). Recently it has been suggested that also green rust minerals, which form during abiotic or microbial Fe(II) oxidation and Fe(III) reduction (Parmar et al., 2001; Pantke et al., 2011; Zegeye et al., 2012) could similarly have been highly reactive iron substrates in the Precambrian oceans (Zegeye et al., 2012). Banded iron formations (BIFs) are major Fe-rich sedimentary deposits of the Precambrian. Because the primary Fe(III) (oxyhydr)oxides that initially formed BIF sediment scavenged trace elements such as Ni from the ocean waters at the time of their precipitation and deposition, they provide an archive of Precambrian ocean chemistry. In this regard, paleomarine reconstructions based on trace element partitioning experiments using abiotic Fe(III) (oxyhydr)oxides as proxies for primary BIF minerals have suggested a decline of oceanic Ni in the late Archean that might have limited methanogens, giving rise to the accumulation of atmospheric oxygen (Konhauser et al., 2009).

The Fe(III) (oxyhydr)oxides used for these previous studies were chemically synthesized. However, in modern environments Fe redox processes are mainly controlled by microbial Fe(II) oxidation and anaerobic Fe(III) reduction (Weber et al., 2006; Konhauser et al., 2011a). It is widely believed that anoxicogenic phototrophic or microaerophilic Fe(II)-oxidizing bacteria were also involved in Fe(II) oxidation and the deposition of BIF primary minerals (e.g., Widdel et al., 1993; Konhauser et al., 2002; Kappler et al., 2005; Planavsky et al., 2009; Chi Fru et al., 2013; Posth et al., 2013b). It has been shown that biogenic Fe(III) (oxyhydr)oxides, consisting of cell–mineral aggregates, differ from abiotic minerals by means of chemical composition, particle size and density (Posth et al., 2010), as well as surface properties (Ferris, 2005; Muehe et al., 2013). The formation of biogenic Fe(III) (oxyhydr)oxides is initiated by a biotic oxidation of Fe(II), and the following hydrolysis of Fe(III) and precipitation of primary minerals is inorganically driven and influenced by the chemical composition and available counter ions in the environment (Clarke et al., 1997; Konhauser et al., 1998; Larese-Casanova et al., 2010). This leads to differences between biogenic and abiotic Fe(III) (oxyhydr)oxides that are caused by the microbial cells and microbially-derived organic compounds, such as extracellular polymeric substances (EPS), present in cell–mineral aggregates. Thus, despite plausible estimates of trace metal concentrations in the Precambrian ocean based on partitioning experiments with chemically synthesized Fe(III) (oxyhydr)oxides, it remains unclear whether microbial cells and organic compounds would have affected the partitioning of Ni and other trace metals. A potential biogenic origin of the primary minerals in BIFs could, therefore, require a re-interpretation of early ocean chemistry and the resultant evolution of the early biosphere.

In this study, biogenic Fe(III) minerals precipitated by the freshwater photoferrotroph Rhodobacter ferrooxidans strain SW2 and the marine photoferrotroph Rhodovulum iodosum were studied in comparison to abiotic Fe(III) minerals with respect to their sorption and co-precipitation capacity for Ni. The spatial distribution of the sorbed and co-precipitated Ni in the cell–mineral aggregates was mapped and the influence of silica (Si) on Ni sorption and co-precipitation was determined, assuming that the Archean ocean was saturated with amorphous Si (e.g., Maliva et al., 2005; Konhauser et al., 2007). Finally, the implications of a potential biogenic origin of Precambrian Fe-rich sediments for Ni abundance in the Precambrian ocean are discussed.

2. EXPERIMENTAL PROCEDURES

2.1. Sources of the organisms

*R. ferrooxidans* strain SW2 was isolated from a freshwater mud sample from a pond in Schaumburger Wald, Hanover region, Germany (Ehrenreich and Widdel, 1994), and *R. iodosum* was isolated from a marine mud flat of the Jadebusen, North Sea, Germany (Straub et al., 1999). Both are Gram-negative purple non-sulfur bacteria belonging to the Alphaproteobacteria and grow photoautotrophically by oxidizing Fe(II) to Fe(III) or by using H₂ as electron donor.

2.2. Microbial growth media and growth conditions

All glassware used for biogenic and abiotic experiments was soaked in 1 M HCl for 24 h and subsequently washed 6 times with MilliQ water to remove traces of metal ions. Both bacterial strains were cultivated in anoxic mineral medium with a reduced phosphate concentration of 0.5 mM. NaCl was added to compensate for the decrease in ironic strength due to the reduced phosphate concentration. The freshwater medium for strain SW2 contained 5.6 mM NH₄Cl, 0.5 mM KH₂PO₄, 5.6 mM NaCl, 0.68 mM CaCl₂·2H₂O, and 2.0 mM MgSO₄·7H₂O. The marine medium for *R. iodosum* contained 4.7 mM NH₄Cl, 0.5 mM KH₂PO₄, 10.2 mM CaCl₂·2H₂O, 27.6 mM MgSO₄·7H₂O, 28.0 mM MgCl₂·6H₂O, 455.9 mM NaCl, 8.9 mM KCl, and 0.8 mM KBr. After autoclaving and cooling under N₂/CO₂ (90/10) gas, 22 mM bicarbonate buffer was added, which had been autoclaved under N₂/CO₂ atmosphere. Then the following solutions were added to the growth media from sterile stocks: 1 mL/L trace element solution SL 10 (Widdel et al., 1983), 1 mL/L vitamin solution...
2.3. Abiogenic samples

Abiogenic ferrihydrite was synthesized by hydrolysis of Fe(NO$_3$)$_3$·9H$_2$O with KOH and subsequently the pH was adjusted to 7.0 as described by Cornell and Schwertmann (2003). The identity of the synthesized ferrihydrite was confirmed by Mössbauer spectroscopy. For sorption experiments, ferrihydrite with the simplified formula Fe(OH)$_3$ was diluted to a final concentration of 2 mM, while for co-precipitation experiments, the synthesis protocol was down-scaled so that only 2 mM ferrihydrite precipitated. This way, the same concentration of ferrihydrite was used for biogenic and abiogenic setups to allow for comparison. The ferrihydrite was synthesized and diluted in MilliQ water, as well as in the freshwater mineral medium as used for the cultivation of strain SW2, or in the marine medium as used for *R. iodosum*. This was done to take into account the ions present in the medium when comparing the biogenic and abiogenic setups.

2.4. Experimental setup

The sorption and co-precipitation of Ni in the presence of biogenic and abiogenic ferrihydrite (2 mM) was determined at pH 6.8–7.0 (see Sections 2.2 and 2.3) in freshwater and marine medium. To a subset of samples, Si was added (2 mM) from a stock of anoxic 50 mM Na$_2$O$_2$Si·9H$_2$O to mimic an early ocean saturated with amorphous Si and to examine the influence of Si on Ni sorption and co-precipitation. Si was added prior to inoculation and before microbial oxidation of Fe(II) or prior to abiogenic ferrihydrite precipitation. Ni (170 μM) was added from a 1000 mg/L Ni ICP standard (in 2% HNO$_3$; Sigma Aldrich). For co-precipitation experiments, Ni was added before inoculation with the Fe(II)-oxidizing bacteria, or prior to abiogenic ferrihydrite precipitation. For sorption experiments, Ni was added after complete microbial oxidation of Fe(II) to Fe(III), or after precipitation of abiogenic ferrihydrite. The samples were equilibrated for 24 h in the dark on a rotary shaker. Duplicates of all cultures and abiogenic samples were set up, in addition to one sterile control per biotic setup. As a control for abiogenic samples, medium without ferrihydrite was used.

2.5. Quantification of Fe, Si and Ni

Fe(II) and Fe(total) were quantified by the spectrophotometric ferrozine assay modified from Stookey (1970) and described by Hegler et al. (2008). Fe(II) and Fe(total) were quantified in all samples prior to inoculation and during microbial Fe(II) oxidation to determine the endpoint of Fe(II) oxidation in biotic samples, and of all abiogenic ferrihydrite samples. Each sample was measured in triplicates. All biotic samples were taken in an anoxic chamber.

The concentration of dissolved Si was determined with the spectrophotometric molybdsilicate method (Eaton et al., 2005). Each sample was measured in triplicates.

The amount of sorbed or co-precipitated Ni was determined by subtracting the final Ni concentration in solution after sorption or co-precipitation from the initial Ni concentration. All Ni concentrations were determined by ICP-OES. In co-precipitation experiments, Ni was added to a final concentration of 10 mg/L (170 μM) to each sample prior to inoculation of the sample with bacteria for biotic samples, and before precipitation of ferrihydrite in abiogenic samples. After complete oxidation of Fe(II) to Fe(III) or abiogenic ferrihydrite precipitation, samples for quantification of final Ni concentrations were filtered using a 0.22 μm nylon filter (Costar, Corning, NY). Aliquots of 990 μL were taken from the filtrate and acidified with 10 μL conc. HNO$_3$.

In sorption experiments, Ni was added to a final concentration of 10 mg/L (170 μM) to each sample after complete oxidation of Fe(II) to Fe(III) or after precipitation of ferrihydrite in abiogenic samples. After 24 h equilibration on a rotary shaker in the dark, samples for quantification of final Ni concentrations were taken and filtered using a 0.22 μm nylon filter (Costar, Corning, NY) in an anoxic chamber. Aliquots of 990 μL were taken from the filtrate and acidified with 10 μL conc. HNO$_3$.

Samples were then diluted 1:10 in MilliQ water and acidified with concentrated HNO$_3$ to 1.5% HNO$_3$. Ni was quantified at a wavelength of 231.604 nm by ICP-OES with a Perkin Elmer Optima 5300 DV equipped with a Meinhard Nebulizer Cyclonic Spray Chamber (non-baffled) for analyses in freshwater medium, and with a Mira Mist Nebulizer for analyses in marine medium. For each setup, two separate samples and a control (see Section 2.4) were measured. Standards for calibration contained the respective medium with a dilution factor of 1:10 as the matrix.

2.6. Mineral characterization

Mössbauer spectroscopy was performed as described previously (Larese-Casanova et al., 2010). In an anoxic glove box, the samples were filtered onto 0.45 μm membranes (mixed cellulose esters) and the minerals preserved between two layers of oxygen-impermeable Kapton tape (Polyfluor Plastics BV, The Netherlands). $^{57}$Fe Mössbauer spectroscopy was performed with a $^{57}$Co source at room temperature with linear acceleration in transmission mode.
The sample temperature was varied using a Janis closed-cycle cryostat with a helium atmosphere. Spectra were calibrated against spectra of α-Fe(0) foil at room temperature and interpreted using Recoil software (University of Ottawa, Canada) and Voigt-based fitting models. For each setup, one sample was analyzed. Estimated errors are ±0.02 mm/s for isomer shift (IS) and quadrupole splitting (QS) values, and ±1 T for hyperfine magnetic field ($B_{hf}$) values.

For specific surface area (SSA) analysis, the abiogenic minerals, biogenic cell–mineral aggregates or bacterial cells grown with $H_2$ were harvested by centrifugation at 4000g and freeze-dried. The SSA of the particles was measured using $N_2$ adsorption by Brunauer–Emmett–Teller (BET) analysis with an ASAP 2000 (Micromeritics) at 77 K after degassing under vacuum for 15–20 h at 40 °C. For each setup, one sample was analyzed.

### 2.7. Scanning transmission X-ray microscopy (STXM)

Samples for STXM were taken after complete oxidation of Fe(II) to Fe(III). Therefore, the samples were not sensitive to oxygen and could be processed underoxic conditions. 1 mL of the culture or abiogenic mineral suspension was sampled and washed carefully twice in Millipore water to eliminate salts and non-sorbed Ni from solution. For samples not containing Si, 1 μL of the resuspended pellet was applied to a silicon nitride window (Norcada Inc., Edmonton, Canada) and air-dried before the window was fixed to an aluminum sample holder. For samples containing Si, a formvar coated 300 mesh Cu transmission electron microscopy (TEM) grid was immersed into the resuspended pellet, air-dried and then fixed to the sample holder.

Most STXM experiments (data shown in Fig. 4a–n and Fig. 5a–h) were carried out at the spectromicroscopy beamline 10ID-1 at the Canadian Light Source (CLS, Saskatoon, Canada), which is described in more detail by Kaznatcheev et al. (2007). Image stack-maps were acquired across the C-1s, O-1s, Fe-2p and Ni-2p edges, and full image sequences (stacks) were acquired across the C-1s and Fe-2p edges with a spectral sampling of 0.1 eV in the energy regions of interest (Hitchcock et al., 2009; Miot et al., 2009a; Table S1).

For the mapping of Si, some additional experiments (data shown in Fig. 5i–q) were carried out at the STXM beamline 11.0.2 at the Advanced Light Source (ALS, Berkeley, CA, USA), which is described in more detail by Bluhm et al. (2006). Here, image stack-maps and image stacks were acquired across the O-1s, Fe-2p, Ni-2p and Si-1s edges with spectral samplings of 0.1 eV (O-1s and Fe-2p) and 0.6 eV (Si-1s) in the energy regions of interest.

The program aXis2000 (Hitchcock, 2013) was used to create quantitative elemental maps. Image sequences were converted from transmission to linear absorbance (optical density, OD; Dynes et al., 2006). Quantitative mapping was done as described previously (Dynes et al., 2006; Hitchcock et al., 2009) by one of three different ways: (i) image difference maps display the difference between two images, one measured at the main absorption peak of the chemical species of interest, the other measured in the pre-edge at an energy below the absorption onset of that species (refer to Table S1 for the energies used). (ii) To reduce statistical noise in image difference maps, the difference between the average of five images measured at the absorption peak and the average of five images measured in the pre-edge is displayed. (iii) In the third, most precise way, image sequences (stacks) at various energies across the desired absorption edge were fitted quantitatively using spectra of known reference compounds, and the optical density converted to effective thickness in nm. Quantification of Ni/Fe was based on the average OD of Ni and Fe in the same region of interest. For quantification, the Ni and Fe maps were threshold-masked to separate absorption signal from statistical noise.

### 3. RESULTS

#### 3.1. Mineral identification and characterization

Before quantification of Ni partitioning in biogenic and abiogenic Fe(III) minerals, we determined their mineralogy, composition and structure. Both biogenic and abiogenic Fe(III) minerals were identified using Mössbauer spectroscopy. The mean magnetic hyperfine field ($B_{hf}$), the quadrupole splitting and the isomer shift measured at different temperatures, identified all biogenic and abiogenic samples precipitated in freshwater or marine medium as ferrihydrite (Fig. S1; Tables S2 and S3). However, an influence on the mineralogy arising from the ions present in the medium was observed, as the $B_{hf}$ of 45.6–46.1 T measured at 4.2 K was lower for ferrihydrite precipitated in marine medium (ionic strength of 0.72 M) as compared to those precipitated in freshwater medium (ionic strength of 0.04 M; Fig. 1) with a $B_{hf}$ of 47.4–48.0 T. This effect was also observed for samples precipitated in the presence of additional Si prior to ferrihydrite precipitation. This result
in an even lower $B_{hf}$ of 44.4–44.5 T for freshwater and 42.2–43.8 T for marine samples (Fig. 1). Ni sorption or co-precipitation did not influence the $B_{hf}$.

The effects of Ni and Si on the mineralogy became more apparent in measurements at 77 K. The magnetic ordering temperature in ferrihydrite generally increases with greater crystallinity and/or particle size, i.e., with the transition from 2-line ferrihydrite to 6-line ferrihydrite. The abiotic 2-line ferrihydrite synthesized in freshwater medium did not show any magnetic ordering at 77 K (Fig. 2a and b) and was used for comparison to biogenic minerals. Biogenic minerals precipitated by *R. ferrooxidans* SW2 in freshwater medium showed the onset of magnetic ordering at 77 K in the absence of Si (Fig. 2c; Table S3), while the presence of Si seemed to prevent this (Fig. 2d; Table S3). A larger extent of magnetic ordering was visible in spectra of ferrihydrite measured at 77 K with sorbed or co-precipitated Ni (Fig. 2e and g; Table S3), while this magnetic ordering effect was also not observed in the presence of Si (Fig. 2f; Table S3).

Interestingly, after sorption of Ni to biogenic ferrihydrite in freshwater medium, 4% and 3% of Fe(II) was detected in the Mössbauer spectra in the absence (Fig. 2e) and presence (Fig. 2f) of Si, respectively (Table S3). The Fe(II) must have formed during the time of incubation with Ni to the time of sample preparation for Mössbauer spectroscopy (20 days), because Ni was added to the cultures only after all Fe(II) had been oxidized to Fe(III), as determined by the ferrozine assay. Fe(II) was not detected for Ni co-precipitation in the

---

**Fig. 2.** Mössbauer spectra, recorded at 77 K, of biogenic and abiotic ferrihydrite precipitated in freshwater medium. Abiogenic ferrihydrite (a, b) was precipitated by hydrolysis of Fe(NO$_3$)$_3$·9H$_2$O with KOH in freshwater medium. Spectra of biogenic ferrihydrite are shown for precipitation in the absence (left c, e, g) and presence (right d, f) of 2 mM Si. Biogenic ferrihydrite was precipitated by oxidation of Fe(II) by the photferroferrothroph *Rhodobacter ferrooxidans* SW2 in freshwater medium without addition of Si in the absence (c) and in the presence of Si (d). After sorption of 10 mg/L (170 lM) Ni to biogenic ferrihydrite, Fe(II) was detected in the spectra (black arrow) in the absence (e) and presence (f) of Si, but was not detected after co-precipitation of Ni with biogenic ferrihydrite (g). For all biogenic samples precipitated in the absence of Si (c, e, g), an increased magnetic order of ferrihydrite is visible, which is absent from samples precipitated in the presence of Si (d, f) or from abiotic samples (a, b). Open circles show the measured data, the solid line represents an overall fit.
freshwater medium (Fig. 2g) or biogenic ferrihydrite precipitated in the marine medium (Fig. S2; Table S3). The formation of Fe(II) will have to be investigated further as this is not the focus of the present study.

The quadrupole splitting recorded at room temperature (Table S2) increased from 0.76 to 0.86 mm/s for biogenic freshwater and from 0.75 to 0.85 mm/s for biogenic marine minerals precipitated in the presence of Si when compared to biogenic minerals formed in the absence of Si.

The specific surface area (SSA) of biogenic ferrihydrite was roughly 2 or 3 times smaller (100 and 130 m²/g) than that of abiogenic ferrihydrite (270 and 220 m²/g) in freshwater or marine medium, respectively (Table 1). The SSA of abiogenic ferrihydrite precipitated in either freshwater or marine medium was in the same range as that for ferrihydrite precipitated in MilliQ water with a value of 280 m²/g. Bacterial cells grown with H₂ and in the absence of minerals exhibited only a low N₂-BET SSA of approximately 1 m²/g (Table 1).

### 3.2. Quantification of Ni sorption and co-precipitation with biogenic versus abiogenic ferrihydrite

After identification of all Fe(III) minerals, Ni sorption to, and co-precipitation with, biogenic and abiogenic ferrihydrite were quantified by ICP-OES by measuring Ni concentrations in solution after Ni partitioning (Table S4). Solid-free control samples showed no loss of Ni to the glass containers. Co-precipitation of Ni led to a higher Ni content in ferrihydrite than sorption in all cases (Fig. 3a). More precisely, Ni co-precipitation with biogenic ferrihydrite in freshwater or marine medium resulted in molar Ni/Fe ratios of 0.032 and 0.017, respectively, and was roughly 3 or 2 times higher than Ni sorption to biogenic ferrihydrite in freshwater and marine samples with molar Ni/Fe ratios of 0.010 and 0.007, respectively (Fig. 3a). Ni co-precipitation with abiogenic ferrihydrite in freshwater medium with a molar Ni/Fe ratio of 0.061 was also 3 times higher than Ni sorption to abiogenic ferrihydrite with a molar Ni/Fe ratio of 0.019. Ni co-precipitation with abiogenic ferrihydrite in marine medium was not determined. Moreover, Ni co-precipitation with, and Ni sorption to, biogenic ferrihydrite in freshwater medium were increased by factors of 2 and 1.4, respectively, compared to Ni co-precipitation with, and sorption to, biogenic ferrihydrite in marine medium. Showing the same trend, the Ni/Fe ratio of 0.019 for Ni sorption to abiogenic ferrihydrite in freshwater medium was 1.7 times higher than in marine medium with a Ni/Fe ratio of 0.011 (Fig. 3a). In addition, Ni sorption and co-precipitation with abiogenic ferrihydrite showed higher values than with biogenic ferrihydrite for both freshwater and marine setups. Specifically, Ni sorption to abiogenic ferrihydrite in freshwater or marine medium was increased by factors 1.8 or 1.5, respectively, compared to biogenic ferrihydrite, while Ni co-precipitation with abiogenic ferrihydrite in freshwater medium was higher than with biogenic ferrihydrite by a factor of 2 (Fig. 3a).

The influence of Si on sorption and co-precipitation of Ni with ferrihydrite was also determined. All trends observed in the absence of Si were confirmed in samples in which Si was present before the precipitation of ferrihydrite, i.e., Ni co-precipitation was higher than Ni sorption (by factors of 4 and 5) for biogenic freshwater and marine samples, respectively. In freshwater medium, sorption and co-precipitation of Ni was higher than in marine medium, and Ni sorption and co-precipitation with abiogenic was higher than with biogenic ferrihydrite (Fig. 3b). Si did not show a significant influence on the amount of Ni sorbed or co-precipitated with ferrihydrite for the chosen concentrations of Fe and Si (see below). In the case of biogenic ferrihydrite in marine medium, the Ni/Fe ratio for Ni sorption decreased by a factor of 2 in the presence of Si, and in the case of Ni co-precipitation with biogenic ferrihydrite in freshwater medium, the presence of Si increased the Ni/Fe ratio by a factor of 1.3. In all other cases, the influence of Si was minor or absent (Fig. 3b).

### 3.3. Spatial distribution of Fe, Ni, Si and protein

STXM was applied to determine the elemental/chemical distribution in the samples. A comparison of the Fe, Ni and protein maps of the biogenic samples with Ni sorption in freshwater and marine medium (Fig. 4a–c and e–g), as well as the illustration in the overlays (Fig. 4d and h), reveals that Ni is associated preferably with ferrihydrite and not with cells (using the protein signal as a proxy for cells). In samples where Ni was sorbed to abiogenic ferrihydrite in freshwater and marine medium, Ni was clearly associated with the minerals (Fig. 4i, k and l, m). For a quantitative evaluation of the image maps, data for Ni co-precipitation were also included (images for Ni co-precipitation not shown). Quantification was based on the average ODs of Fe and Ni in the same region of interest and showed that Ni/Fe ratios for Ni co-precipitation were higher than those for Ni sorption in all cases, that Ni/Fe ratios for all freshwater samples were higher than those for marine samples in both biogenic and abiogenic setups, and that Ni/Fe ratios for abiogenic ferrihydrite were higher than those for biogenic ferrihydrite in both freshwater and marine medium (Fig. 4n). This trend on the microscopic scale is in good agreement with the data obtained by ICP-OES (Fig. 3a).
values in values can be a result of (a) substitution also decreases. Substitution also decreases values when the particles domain sizes are comparable to particle sizes and are then show superparamagnetic behavior, i.e., the magnetic moment becomes smaller than approximately 30 nm. The particles do not lead to any changes in the Mössbauer parameters. occluded, does not alter the crystal structure and therefore does not lead to any changes in the Mössbauer parameters.

However, the values themselves should not be directly compared because they were based on OD-ratios for STXM and on molar ratios for ICP-OES analyses.

In the presence of Si, only biogenic samples with ferrihydrite precipitated by *R. ferrooxidans* SW2 in freshwater medium were analyzed by STXM. Comparing Fe and protein maps shows that in the presence of Si, Fe was directly associated with the cells in a few cases (Fig. 5a, c and e, g). This phenomenon was observed in two separate cultures analyzed (samples shown in Fig. 5a–d stemming from one culture, samples shown in Fig. 5e–h stemming from a separate culture) in the presence of Si, while co-localization of cells and Fe was not observed in samples which did not contain Si (Fig. 4a, c and e, g). Energies at the CLS did not allow the mapping of Si directly. However, a high absorption in the C-1s pre-edge at 280.0 eV (Bearden and Burr, 1967) are in the C-1s pre-edge. Ni in these samples was co-located with Fe, and where Fe was associated with protein, Ni was co-located with protein as well. However, it should be noted that these cells did not represent the bulk of the samples. Due to the limited available beamtime, we were unable to analyze all sample spots in detail, and had to prioritize the analysis of certain regions of interest based on a coarse sample screening. These Fe-associated cells represented noticeable exceptions. These Fe-associated cells represented noticeable exceptions. For a better understanding of the influence of Si, another sample was analyzed at a subsequent shift of beamtime at beamline 11.0.2 at the ALS. In this case, a coarse scan of this sample did not find cells associated with Fe, but Si clearly co-located with Fe in this sample (Fig. 5i, l and n, p) and not with protein, which is nicely demonstrated by the overlays in Fig. 5m and q.

4. DISCUSSION

4.1. Mineralogy of biogenic and abiotic Fe(III) minerals

In this study, sorption of Ni to, and co-precipitation with biogenic and abiotic ferricydrite in both freshwater and marine setups. (b) Ni sorption to and co-precipitation with biogenic and abiotic ferricydrite in freshwater and marine setups in the presence and absence of silica. Error bars indicate the range of values of two independent samples. Where no error bar is present, only one sample was analyzed. Fh, ferricydrite (abiogenic Fh was precipitated by hydrolysis of Fe(NO3)3·9H2O by KOH); FM, freshwater medium; MM, marine medium. investigated. All biogenic and abiotic Fe(III) minerals were identified as ferricydrite by Mössbauer spectroscopy, regardless of the medium that they were precipitated in (freshwater or marine) and independent of the presence of Ni and Si. Previous findings of the formation of goethite by strain SW2 (Kappler and Newman, 2004; Posth et al., 2010) could not be confirmed in the present study. *R. iodosum* has been shown before to precipitate mostly ferricydrite in unfiltered medium, with traces of magnetite (Straub et al., 1999).

Despite all minerals being identified as ferricydrite, an influence of the media solution chemistry on the ferricydrite structure and crystallinity was observed. The *Bhf* values in the 5 K spectra of ferricydrite precipitated in marine medium (Table S2) are generally lower than those reported for ferricydrite prepared in the laboratory (Bhf between 47 and 50 T; Murad and Cashion, 2004). However, they are comparable to those reported from natural samples recovered from marine environments (Chakarova et al., 2013). A decrease of *Bhf* values can be a result of (a) substitution of Fe by other cations or vacancies, or (b) a decrease in particle size. Cations or vacancies substituting for Fe have a magnetic moment that is different from that of Fe or no magnetic moment at all. As a result, the magnetic ordering temperature is generally lowered and the resulting internal magnetic field *Bhf* decreases. Substitution also distorts the crystal structure, as the substituting ions have a different radius and/or valence state, which needs to be balanced by vacancies elsewhere. The QS parameter in spectra above the magnetic ordering temperature, i.e., where sextets in the Mössbauer spectra have collapsed to doublets, is a measure of structural symmetry. It should increase upon substitutions that alter the structure (e.g. Rancourt et al., 2001; Eusterhues et al., 2008). By contrast, sorption of elements or ligands to the surface of ferricydrite, even if occluded, does not alter the crystal structure and therefore does not lead to any changes in the Mössbauer parameters.

Particle size can affect *Bhf* values when the particles become smaller than approximately 30 nm. The particles then show superparamagnetic behavior, i.e. the magnetic domain sizes are comparable to particle sizes and are flipped randomly through thermal activity of the particles
which results in a net zero magnetic field. Magnetic ordering can be restored by lowering the temperature, and this so-called blocking temperature decreases as the average particle sizes become smaller. In the case of very small particles it may be that the blocking temperature is close to 5 K, in which case full magnetic ordering is not yet restored at 5 K, resulting in the observation of decreased $B_{hf}$. We generally observe lower $B_{hf}$ values in the marine medium samples compared to the freshwater medium samples. Excluding the Si-coprecipitation experiments, we do not observe an increase in QS values in the 77 K or RT spectra. Surface areas derived from BET measurements (Table 1) are not generally smaller for ferrihydrite precipitated in marine medium. We conclude from these observations that ferrihydrite precipitated in the marine medium had substitutions of Fe by other elements but with minimal structural change. That requires substitution of Fe$^{3+}$ by other ions of the same valency, for example Al$^{3+}$. Different bacterial strains do not influence the ferrihydrite crystal structure as we do not observe any significant differences in the Mössbauer parameters between biogenic and abiotic ferrihydrite precipitated in the same medium.

In spectra from the Si-coprecipitation experiments we observe a further and very significant decrease in $B_{hf}$ values in marine medium, a similar significant decrease in $B_{hf}$ values in freshwater medium, and a significant increase in QS values in both marine and freshwater media. We therefore conclude that some Fe$^{3+}$ has been substituted by Si$^{4+}$ in these experiments. In addition, we do not observe any difference in the Mössbauer parameters between experiments in the presence or the absence of Ni, nor do we observe any significant differences between Ni sorption and Ni
coprecipitation experiments. This further suggests that Ni sorbs to ferrihydrite surfaces and might be occluded but is not incorporated into the crystal structure.

We also observed the onset of magnetic ordering, i.e. the emergence of sextets, in 77 K spectra of biogenic ferrihydrite precipitated by SW2 in freshwater medium. This implies that, compared to the abiogenic ferrihydrite, the biogenic ferrihydrite has slightly higher crystallinity or particle size. The medium composition can be excluded as the determining factor because in that case the abiogenic ferrihydrite synthesized in freshwater medium should have also shown an increased magnetic ordering, but this was not the case.

The fact that increased magnetic order was not detected at 77 K for biogenic ferrihydrite precipitated in marine medium by R. iodosum also rules out microbiologically-derived organic compounds or cells as the cause for an increased magnetic order; in particular since organic substances are typically known to decrease the magnetic order of ferrihydrite (Schwertmann et al., 2005; Mikutta et al., 2008). However, the rate and mechanism of ferrihydrite precipitation can probably explain the increased magnetic order at 77 K of biogenic ferrihydrite precipitated by the freshwater strain SW2. While abiogenic ferrihydrite was formed by rapid hydrolysis of Fe(NO₃)₃·9H₂O with KOH within minutes, the biogenic ferrihydrite was produced by slow microbial oxidation of Fe(II) over a time span of at least 14 days. This slow formation of ferrihydrite allows more time for slow crystal formation and may lead to a slightly more crystalline structure as indicated by the increased magnetic order (Cornell and Schwertmann, 2003). However, in the environment, ageing of minerals may equalize crystallinity of both mineral synthesis routes on a time scale relevant for sedimentation and mineral deposition. This would leave the slightly higher crystallinity of biogenic ferrihydrite observed under laboratory conditions with only minor importance for an ancient ocean scenario. Moreover, the high concentrations of seawater ions of the marine medium seemed to interfere with crystal formation and prevent an increased magnetic order at 77 K in biogenic and abiogenic ferrihydrite. Also in the presence of Si, an increased magnetic order was not observed at 77 K. Si is known to form
strong and stable complexes on ferrihydrite surfaces, thereby interfering with crystal formation and crystal growth (e.g., Doelsch et al., 2000; Pokrovski et al., 2003; Cismasu et al., 2011). Indeed, the effect of Si interfering with crystal formation in our study could be inferred from the increased quadrupole splitting.

The specific surface area (SSA) of the minerals was determined by BET measurements to estimate the available surface area for Ni sorption. We found that the medium in which the ferrihydrite was precipitated did not influence the SSA significantly. The lower SSA of biogenic (100–130 m²/g) as compared to abiogenic ferrihydrite (220–270 m²/g) is in agreement with the higher crystallinity of biogenic ferrihydrite synthesized in freshwater medium as observed by Mössbauer spectroscopy. However, it has to be kept in mind that BET sample preparation could have changed the particles and available surface area. The vacuum drying and degassing might lead to (partial) blocking of the ferrihydrite surface and micropores by microbially-derived organic substances or whole cells which themselves exhibit a negligibly low N₂-BET SSA (~1 m²/g). As a consequence, this suggests a smaller mineral surface than what actually exists under wet conditions.

### 4.2. Ni sorption and co-precipitation with biogenic versus abiogenic ferrihydrite

Ni partitioning in biogenic and abiogenic ferrihydrite was determined by quantifying dissolved Ni concentrations after sorption or co-precipitation. A total Ni concentration of 10 mg/L (170 μM) was chosen based on previous experiments that showed that such concentrations are necessary for successful detection with STXM (Hitchcock et al., 2009). It should be noted that this concentration is vastly in excess of natural marine waters where Ni concentrations are around 9 nM, and even higher than estimated Archean seawater concentrations of 400 nM (Konhauser et al., 2009).

We found that Ni co-precipitation with ferrihydrite was roughly 2–3 times higher than Ni sorption in all setups. This is probably due to the fact that in the Ni sorption experiments Ni can bind only to the mineral surface sites that are available after complete oxidation of Fe(II) and Fe(III) mineral precipitation. In contrast, Ni co-precipitation includes Ni sorption to constantly forming new surface sites and occlusion by the forming crystals during precipitation, thereby removing more Ni from solution than sorption. An incorporation of Ni ions into the crystal lattice of hydrous ferric oxide (HFO) has not been observed (Xu et al., 2007). The high ionic strength of marine medium also led to lower Ni/Fe ratios in ferrihydrite precipitated in the marine medium compared to the Ni/Fe ratios in ferrihydrite precipitated in freshwater medium. In the marine medium, other divalent cations present in high abundance, such as Mg²⁺ and Ca²⁺, but also anions such as HCO₃⁻, will compete with the Ni and reduce the ability of Ni to bind to the surface of ferrihydrite.

The most interesting difference in Ni sorption and Ni co-precipitation was observed for biogenic compared to abiogenic ferrihydrite. While the concentration of sorbed or co-precipitated Ni is slightly higher for biogenic as compared to abiogenic ferrihydrite when normalized to the respective SSA (Table S5), the overall observed Ni sorption (and co-precipitation as a mechanism including sorption) is lower for biogenic ferrihydrite when looking at the molar Ni/Fe ratios (Fig. 3). This is in agreement with the higher crystallinity of biogenic ferrihydrite as observed by Mössbauer spectroscopy, and is also consistent with the higher SSA of abiogenic ferrihydrite. However, as discussed in Section 4.1, results of BET measurements of biogenic ferrihydrite have to be regarded with care as vacuum drying might lead to artefacts with organics or cells blocking sorption sites and micropores, thereby distorting the actual SSA of the mineral.

Regardless of the accuracy of the SSA, microbially-derived organics or whole cells in biogenic ferrihydrite bind to the mineral surface and compete with the Ni for sorption sites, explaining the lower sorption of Ni to biogenic ferrihydrite. Additionally, as shown by STXM, in the biogenic ferrihydrite (consisting of cell-Fe(III) mineral aggregates) Ni was co-localized with Fe, but not with the bacterial cells or other organic substances. This is in agreement with a study of an environmental biofilm, in which Ni was associated with the Fe-encrusted sheaths of filamentous bacteria, but not with bacterial cells that were unmineralized (Hitchcock et al., 2009).

The question is why does Ni preferably sorb to ferrihydrite mineral surfaces and not to the microbial cell surfaces? Metal sorption to cells or to Fe(III) (oxyhydr)oxides is based on proton exchange reactions. The proton-active sites on the cell wall of Gram-negative anoxygenic phototrophs are carboxyl, phosphoryl, phosphodiester and amine moieties (Pokrovsky et al., 2013), of which the carboxyl and phosphoryl moieties are deprotonated at neutral pH, as present in our experiments. In a previous study applying surface complexation modeling using a Linear Programming Model approach (LPM) described by Martinez et al. (2004), Pokrovsky et al. (2013) determined binding constants for Ni adsorption to the cell wall of an anoxygenic phototroph with pK values of ~1.45 ± 0.05, 0.35 ± 0.05 and 5.0 with site densities of 0.418, 0.34 and 0.0287 μmol/g wet biomass, respectively (Pokrovsky et al., 2013). In comparison, pK values of ~3.25 to 2.50 have been determined by surface complexation modeling for Ni sorption to hydrous ferric oxide with a confidence level of 0.99 and a total binding site density of 0.2 mol/mol for weak and 0.005 mol/mol for strong binding sites (corresponding to 2222 and 55.5 μmol/g HFO, respectively (Dzombak and Morel, 1990)). The lower pK values for Ni sorption to HFO and the higher binding site density on the mineral surface as compared to the cell wall allow a higher affinity of Ni for HFO and can explain the preferential sorption of Ni to ferrihydrite in cell–mineral aggregates in the present study. It has to be kept in mind, however, that their experiments were performed with washed cell or mineral suspensions in a NaNO₃ electrolyte and the values are not directly comparable to our studies in which media containing other potentially interfering ions were used.

Extended X-ray absorption fine structure (EXAFS) studies of Ni sorption to Fe(III) (oxyhydr)oxides have
shown that Ni mostly forms edge-sharing surface complexes with inner-sphere mononuclear bidentate coordination (Xu et al., 2007; Arai, 2008). Corner-sharing surface complexes with inner-sphere mononuclear monodentate coordination have also been detected in minor abundance (Arai, 2008). While EXAFS studies on biogenic cell–Fe(III) mineral aggregates have not yet been performed, EXAFS data of Ni sorption by biomass–birnessite assemblages at pH 7 led to estimations of fractional contributions of Ni sorption to birnessite (0.30), Ni sorption to biomass (0.45) and Ni precipitation as Ni(OH)₂ (0.23) by linear combination fitting (Peña et al., 2011). Those authors concluded that biomass does not block reactive surface sites on the mineral, but that it contributes to Ni sorption at high metal loading when high-affinity sites on the mineral surface are saturated or unavailable. It should be noted that the Ni/sorbent ratio used in their study was ten times higher than in our study and moreover, the Mn(II)-oxidizing bacterium Pseudomonas putida was grown in a nutrient-rich medium, likely to much higher cell densities than the photoferrotrons in our study. The higher Ni loadings and higher contribution of cell surfaces to the overall available reactive surface sites could be a possible explanation for their observation that biomass contributed to Ni sorption, which is in contrast to our observations where the Ni was mostly associated with the Fe minerals and not the biomass. A blocking of reactive mineral surface sites by microbial cells and their organic compounds in combination with lower Ni affinity to the cell surface sites as compared to Fe(III) (oxyhydr)oxide mineral surface sites best explains our observations.

4.3. Influence of Si on Ni partitioning in biogenic versus abiogenic ferrihydrite

In most experiments, the presence of Si during ferrihydrite precipitation did not significantly influence Ni sorption or co-precipitation with ferrihydrite on a quantitative basis, although local heterogeneities were observed. This is in contrast to previous studies in which Ni showed attenuated sorption to ferrihydrite by one order of magnitude in the presence of Si due to Si competing for sorption sites (Konhauser et al., 2009). These differences can potentially be explained by the applied Si/Fe ratios; the previous study used a Si/Fe ratio of 12:1 (Konhauser et al., 2007, 2009) which is representative for the Archean ocean (0.02–0.5 mM Fe; Holland, 1973; Morris, 1993; 2.2 mM Si; Maliva et al., 2005), while a higher Fe concentration (2 mM) was used in our study to ensure microbial growth necessary for visualization of cells by STXM, yielding a Si/Fe ratio of 1:1. Indeed, the spatial distribution of Fe, Si and Ni analyzed by STXM showed a co-localization of Fe and Si, confirming the potential blocking of Fe mineral sorption sites for Ni by Si, as might be expected at the much lower Fe concentrations of the Archean oceans. Therefore, the higher Fe content in our experiments provided sufficient surface area and thus sorption sites for both Ni and Si, so that the Si did not influence Ni sorption. This is supported by a previous report demonstrating that at a concentration of 2 mM Fe, the role of 2 mM Si for phosphate sorption to ferrihydrite becomes negligible (Konhauser et al., 2007), which seems to be consistent with our findings. Moreover, as mentioned above, this study used Ni/Fe ratios 4× higher than in the study by Konhauser et al. (2009), leading to Ni/Fe ratios in the solid products above 0.01 versus 0.0025 for Si-rich particles in Konhauser et al. (2009). Accordingly, our use of higher Ni concentrations here facilitated greater Ni sorption. However, sorption isotherms indicate that an increase of the Ni/Fe ratio by a factor of 4 at these high Ni concentrations leads to an increase of the amount of adsorbed Ni by approximately a factor of 2–2.5 (Fig. S3).

Despite the negligible effect of Si on dissolved Ni concentrations in our experiments here, STXM analyses did reveal effects of Si at a small-scale in biogenic ferrihydrite. These samples showed heterogeneities with respect to cell encrustation, with some cells being encrusted in a mineral containing Fe and Si, while others were not encrusted at all. It has been shown before that phototrophic Fe(II)-oxidizers do not, or at least not to a large extent, encrust in the Fe(III) (oxyhydr)oxide minerals they precipitate (Kappler and Newman, 2004; Jiao et al., 2005; Miott et al., 2009b; Schädler et al., 2009; Hegler et al., 2010; Posth et al., 2010). This is due to an acidic microenvironment around the cell that prevents Fe(III) mineral precipitation on their cell wall, probably in combination with the excretion of EPS that function as nucleation centers distal to the cells (Kappler and Newman, 2004; Schädler et al., 2009; Hegler et al., 2010; Saraiva et al., 2012). This raises the questions of why and how do some of the cells get encrusted in our experiments, whether the Si binds directly to the cell surface or to ferrihydrite encrusting the cells, and whether Fe–Si minerals are formed? In previous studies of an environmental biofilm, Si was co-located with the Fe-rich sheaths of filamentous bacteria, but was interpreted as organosilicate based on spectroscopic C–O–Si bond signals (Hitchcock et al., 2009). While direct Si binding to cell surface sites has been demonstrated in lab experiments (Urrutia and Beveridge, 1993; Toporski et al., 2002), environmental samples from hot springs, hydrothermal vents and freshwater biofilms showed that an initial binding of Fe cations to anionic cell surface sites, followed by Fe mineral precipitation and reaction of Si(OH)₄ with Fe mineral surface hydroxyl groups (Juniper and Fouquet, 1988; Konhauser et al., 1993, 1994, 1998; Konhauser and Ferris, 1996) or sorption of Si to Fe-rich microbial sheaths (Köhler et al., 1994), facilitates silica sorption. In other words, Fe acts as a cation bridge for silica precipitation on microbial surfaces (Phoenix et al., 2003). In our experiments, the increased quadrupole splitting observed in Mössbauer spectra of biogenic ferrihydrite precipitated in the presence of Si indicates the incorporation of Si into the crystal lattice of ferrihydrite. This suggests the encrustation of the cells by a Fe–Si co-precipitate (siliceous ferrihydrite). As metabolically active phototrophic Fe(II)-oxidizing bacteria were shown not to encrust, and since we observed only a few encrusted cells, we believe that a small fraction of dead cells in our cultures were not able to actively maintain their acidic microenvironment, thereby facilitating mineral precipitation on the cell wall. This is consistent with other studies that have shown live,
dormant, moribund and dead cells differing in their mineralization behavior (Urrutia et al., 1992; Toporski et al., 2002). In support of this, dead cells show an increased availability of functional groups capable of metal binding as a result of cellular degradation (Ferris et al., 1988).

4.4. Implications for ancient environments

BIFs preserve an archive of early ocean chemistry due to the scavenging of trace metals by the precipitating Fe(III) (oxyhydr)oxides during the oxidation of dissolved Fe(II). Experimentally-derived partition coefficients of these trace metals and comparison to trace metal concentrations in BIFs have been used to estimate their dissolved concentrations and bioavailability in the early ocean. This allows us to draw conclusions regarding microbial activity and the evolution of the biosphere at the time of mineral deposition based on trace metal requirements of modern organisms (Bjerrum and Canfield, 2002; Konhauser et al., 2007, 2009; Robbins et al., 2013). One study suggested that phosphate sorption onto Fe(III) (oxyhydr)oxides would have led to phosphate limitation and reduced oxygen production by phototrophic organisms, resulting in a delay in atmospheric oxygenation during the late Archean (Bjerrum and Canfield, 2002). This theory was challenged by experiments considering elevated Si concentrations (2.2 mM; Maliva et al., 2005), consistent with the lack of a biological Si removal in early oceans, that showed that Si would have out-competed phosphate for binding to Fe(III) (oxyhydr)oxides, rendering the so-called “Archean phosphate crisis” unlikely (Konhauser et al., 2007; Planavsky et al., 2010b). Subsequent studies estimated Archean ocean Ni and Zn concentrations based on partitioning of these elements in Fe(III) (oxyhydr)oxides in the presence of Si (Konhauser et al., 2009; Robbins, 2013). However, all these studies used chemically synthesized Fe(III) (oxyhydr)oxides as a proxy for naturally occurring Fe minerals, despite the potential for a biogenic origin of primary minerals in BIFs (e.g., Widdel et al., 1993; Konhauser et al., 2002; Kappler et al., 2005; Johnson et al., 2008; Posth et al., 2008; Planavsky et al., 2010a).

Biogenic Fe(III) (oxyhydr)oxide minerals differ from abiogenic minerals due to the presence of microbially-derived organic material (e.g. Ferris, 2005; Posth et al., 2010), and in the present study, we demonstrated that biogenic ferrihydrite sorbed and co-precipitated more Ni than biogenic ferrihydrite. A previous study that used chemically synthesized Fe(III) (oxyhydr)oxides as proxies for primary BIF minerals calculated Ni concentrations in the Archean ocean to have dropped from 400 nM to below 200 nM by 2.5 Ga ago (Konhauser et al., 2009), thereby limiting methanogen activity since several enzymes in methanogens require Ni as a co-factor. Observations that Ni concentrations below 100 nM lead to reduced methanogen cell numbers (Schönheit et al., 1979) and methane production decreased at 250 nM Ni (Kida et al., 2001) agree with a potential methanogen famine when Ni concentrations dropped to 200 nM at the end of the Archean. Taking into account our data that showed that Ni sorption to biogenic ferrihydrite was two to three times lower than to abiogenic minerals, and assuming a biogenic origin for at least a part of the primary BIF minerals, it is possible that the Ni concentration in the Archean oceans may have been even higher than previously thought. This has two implications. First, it supports the premise that the Archean oceans could have supported an extensive methanogen community, not only in the bottom sediments, but presumably throughout much of the water column. Indeed, the $^{13}$C content of preserved organic carbon in various sedimentary lithologies ca. 2.70 Ga has been used to argue for methane-dominated ecosystems in both shallow- and deep-water environments at that time (Eigenbrode and Freeman, 2006). Second, Konhauser et al. (2009) proposed that dissolved Ni concentrations dropped below a critical threshold for methanogens in the water column shortly after 2.7 Ga, but if marine Ni concentrations were actually higher than initially assumed, then the methanogen famine could have been delayed to just prior the Great Oxidation Event at ca. 2.45 Ga (Konhauser et al., 2011b). This implies that the progression from an anoxic to oxic water column, and ultimately the transition from an anoxic to oxic atmosphere, might have taken place within tens of millions of years.

However, comparing the data of our study to those presented by Konhauser et al. (2009) requires caution. While Konhauser et al. (2009) used concentrations of Ni (0–4000 nM) and Fe (0.179 mM) believed to be representative for the Archean ocean (Ni: 400 nM, Konhauser et al., 2009; Fe: 0.02–0.5 mM, Holland, 1973; Morris, 1993), the concentrations used in our study were constrained by experimental limitations: a concentration of 2 mM Fe(II) was used for microbial Fe(II) oxidation to grow enough cells for a visualization with STXM, and 10 mg/L (170 μM) Ni were required to be above the quantification limit for STXM analysis (Hitchcock et al., 2009). Using these particular concentrations (especially Fe concentration) excludes a Si/Fe ratio relevant for the Archean ocean and does not allow drawing direct conclusions on the effects of Si on the partitioning of Ni in ferrihydrite in ancient environments.

5. CONCLUSIONS

Our experiments have demonstrated that the sorption and co-precipitation of Ni with ferrihydrite are reduced by the presence of microbially-derived organics and by ions present in marine medium. Silica co-precipitated with the ferrihydrite, but did not quantitatively influence the amount of Ni sorbed or co-precipitated at the Fe, Ni and Si concentrations tested. Since naturally occurring Fe(III) (oxyhydr)oxides contain similar impurities (e.g., Cismasu et al., 2011), considering organic material and interfering ions in experimental model systems is critical for a better understanding of the availability and fate of trace metals in modern and ancient natural environments. To obtain a full picture of the fate and bioavailability of trace metals in ancient oceans, however, remobilization processes such as microbial (Zachara et al., 2001; Crowe et al., 2007) and abiotic (diagenetic) mineral transformation processes (e.g., Friedich et al., 2011; Köhler et al., 2013; Posth et al., 2013a; Robbins, 2013) have to be considered as well.
ACKNOWLEDGEMENTS
