

Network-Mediated Knowledge Spillovers in ICT/Information Security

June, 2019

Neil Gandal
Nadav Kunievsky
Lee Branstetter

Abstract. A large literature has used patent data to measure knowledge spillovers across inventions but has not explicitly considered the collaboration networks formed by inventors as a mechanism for shaping these knowledge flows. This paper develops a method to measure the incidence and nature of knowledge flows mediated by the collaboration networks of inventors. We apply this methodology to the information and communication technology (ICT) and information security sectors in Israel and find that the quality of Israeli ICT inventions are systematically linked to the structure of the collaborative network.

We thank the Maurice Falk Institute for Economic Research in Israel and Start-Up Nation Central for financial support of this research. We thank Britta Glennon for excellent research assistance. We are especially grateful to Tim Bresnahan for very helpful comments and suggestions that significantly improved the paper. We also thank Eugene Kandel and seminar/conference participants at the 19th CEPR IO conference, the 10th Paris conference on Digital Economics, Collegio Carlo Alberto, Hebrew University, Stanford University, Tel Aviv University, and UC-Berkeley and for helpful comments and suggestions.

1. Introduction

Knowledge spillovers lie at the heart of modern theories of endogenous growth (Romer, 1986, 1990; Acemoglu, 2009), international trade (Grossman and Helpman, 1991; Branstetter and Saggi, 2011); international investment (Keller and Yeaple, 2013), and economic development (Jones, 2014). The late Zvi Griliches and several generations of his students, including Adam Jaffe and Manuel Trajtenberg (2002), introduced a series of econometric techniques for empirically measuring the strength of these spillovers across time and space, using patents and patent citations. A large and growing literature has deployed these techniques across a wide range of technological domains, organizational categories, and countries, strongly affirming the existence and importance of knowledge spillovers.¹

Despite this extensive literature, the exact mechanisms through which knowledge spillovers are propagated, their relative importance in mediating these knowledge flows - and the effects of these spillovers on the quality of the end products - remain imperfectly understood. Some early research (Griliches, 1979, 1992; Keller, 1998) presumed that at least some spillovers might flow through contact in the marketplace with products or services embodying new technology. Other firms might reverse-engineer and build on this technology without ever forging any direct contact between their R&D engineers and those of the firm that created the original product. While this kind of spillover is certainly possible, in modern technology-intensive industries, spillovers are also likely to occur through more direct interaction between individuals who work together and exchange ideas and information.

High-tech R&D is typically done by teams. Working in teams necessarily involves exchanging ideas and sharing information. Participants of such research teams carry this knowledge to other teams and other projects in which they are involved or become involved, and knowledge can continue to flow between former collaborators even after they move across regions or to different firms and cease direct collaboration (Almeida et al., 2001; Agrawal et al., 2006). The networks traced out by collaborations can become a key mechanism through which knowledge flows (Afcigit et al., 2018). Interestingly, though a great deal of research has focused on

¹ The empirical literature on knowledge spillovers is quite extensive, and we lack the space to review it fully. Scherer (1982), Jaffe (1986), Bernstein and Nadiri (1988), and Irwin and Klenow (1994) authored influential early studies, and Griliches (1992) provided a survey of early empirical work. Keller (2004) provides a review of the empirical literature focused on international knowledge spillovers, which is not the focus of the current paper.

measuring knowledge spillovers in patents, over time and space, to the best of our knowledge, fewer papers have tried to link the structure of the networks formed by inventors' prior collaborations to the quality of the patents they generate.

In this paper, we employ a simple model to examine the existence and importance of collaborator network-mediated knowledge spillovers in the ICT/information security industry in Israel, a leading force in the ICT industry. Like the other papers in this literature, we assume that the quality of a patented invention is closely related to its count of forward citations.

In order to apply the model, we have to address the issue that patent networks form sequentially and therefore play a dual role in expanding the number of citations received by a given patent. First, the denser and richer the patent network available to the inventors is at the time of the patent application, the more access the inventors have to useful knowledge obtained through their prior collaborations, both direct and indirect. This enhances the quality and value of invention i , and hence leads to more citations. We refer to this effect as the “ex-ante” knowledge spillover. After invention i is generated, the evolving network propagates knowledge of this useful invention (and the technical innovations it contains) to other inventor teams working on related technologies, leading to more citations over time. We refer to this as the “ex post” effect. We are primarily interested in the first, “ex ante” effect. To the best of our knowledge, we are the first to both identify and measure this “ex ante” effect on the quality of individual inventions.

Using data from U.S. PTO patent grants in information security, we find that the quality of Israeli ICT/information security inventions is systematically linked to the structure of the collaborative network that existed among Israeli engineers at the time of the patent application. In particular, we find positive and statistically significant “ex-ante” direct and indirect knowledge spillovers among Israeli inventors. This research highlights the importance of direct interaction among inventors as a conduit for flows of frontier scientific knowledge.

We also repeated the analysis for (I) Financial Technology (Fin-Tech) and (II) Medical Technology (Med-Tech) again using Israeli data. Like ICT, Fin-Tech and med-Tech are also areas of innovation that require computer science expertise and programming skills, areas in which Israel should have a comparative advantage. In the analysis, we use data from the United

States Patent and Trademark Office (USPTO.) Unlike ICT, we find no evidence of spillovers in either Fin-Tech or Med-Tech.²

1.1 Literature Review

Our paper is related to two strands of literature. The first strand, pioneered by Trajtenberg (1990), uses patent citations as measures of the quality of innovations and as measures of knowledge spillovers across inventions. More important inventions tend to be cited more frequently by subsequent patents, in the same way that important and influential papers receive more citations from later scholarship. Empirical techniques initially developed by Jaffe, Trajtenberg, and Henderson (1993) and reviewed in Jaffe and Trajtenberg (2002) use patent citations to measure knowledge spillovers across time and space. As this literature evolved, a growing number of papers sought to directly measure social, contractual, or institutional connections between inventors that might mediate knowledge spillovers between them. Branstetter (2001, 2006), Singh (2008), Berry (2012), and Alcacer and Zhao (2012), among others, built on the techniques of Jaffe, Trajtenberg, and Henderson, and used them to measure the degree to which multinationals can enhance flows of knowledge spillovers across national boundaries by creating R&D facilities abroad. Gomes-Casseres, Hagedoorn and Jaffe (2006) and Branstetter and Sakakibara (2002) have used patent and citation data to measure the impact of formal interfirm research collaboration on knowledge spillovers. Almeida et al. (2001) and Agrawal, Cockburn, and McHale (2006), among many others, have sought to measure the impact of the movement of specific individual inventors across organizational boundaries on knowledge spillovers between them. Interestingly, however, virtually no previous studies in the economics literature have examined the impact of inventors' collaboration networks traced out by coinventions (that is, inventors appearing together on the same patent document) on knowledge flows and invention quality.³

² One possible explanation for the Fin-tech and Med-tech results is that the connected networks formed in Elite Israel Defense Force (IDF) units, such as the well-known Unit 8200, play an important role in seeding successful ICT/IS startups in Israel by creating a connected network of programmers. Unit 8200, a military intelligence unit focusing on signal intelligence and code decryption, is the largest unit in the Israel Defense Forces, comprising several thousand soldiers. Once they leave the military, 8200 veterans use the network of 8200 veterans to found start-ups and develop ICT/IS technologies based in part on their experience and connections in the military. Such effects are not likely present in the Med-tech and Fin-tech categories.

³ Breschi and Lissoni (2009) provide an exception. Their question and approach differs from ours. They are primarily interested in distinguishing knowledge flows that are due to (1) local proximity versus those due to (2) inventors who move from firm to firm locally. While they build a co-invention network, they do not formally use the properties of the network in the analysis, and do not link structural characteristic of the network to the quality of patents.

This omission in the innovation literature is striking given the significant attention placed on collaboration networks in other, closely related social science literatures. Recent studies have examined the relationship between network structure and behavior (e.g., Ballester, Calvo-Armengol, & Zenou, 2006; Calvo-Armengol & Jackson, 2004; Goyal, van der Leij and Moraga-Gonzalez, 2006; Jackson & Yariv, 2007; Karlan, Mobius, Rosenblat, & Szeidl, 2009) and the relationship between network structure and performance (Ahuja, 2000; Calvo-Armengol, Patacchini, & Zenou, 2009, Fershtman and Gandal, 2011, and Gandal and Stettner, 2016).⁴

Schilling and Phelps (2007), and a related stream of papers, examine alliance structures among firms, showing that firms with denser alliance networks generate more patent applications. Analysis is at the firm level, not the inventor level, and it is firm alliance structures, not coinventions, that forms the basis for the network. Patent counts are used as the innovative outcome, but are not adjusted for citations. Paruchuri's (2010) work is somewhat closer to the approach taken in this paper. Paruchuri examines the relationship between the centrality of inventor in a pre-existing ("ex ante") intrafirm coinventor network and the placement of the firm in an interfirm research alliance network. This paper does consider invention quality, but looks only at patent citations received only by inventors in the same firm (self-citations) and limits its purview to only eight firms in the pharmaceutical industry. Hence, it is essentially a case study.

Perhaps the closest prior work to our own is Fleming, King, and Juda (2007), who examine regional innovation networks within the United States. They focus most intensively on Silicon Valley and Boston, using data from the late 1970s through the late 1990s, and explore the hypothesis that so-called "small world" network structures contribute to innovative outcomes. In general, they find much less evidence for this than expected. These authors find that the number of patented inventions generated by the regional cluster is positively related to the size of the giant component and negatively to path length within the component, but analysis is conducted at the cluster level rather than at the patent level.

⁴ There is a separate economic literature on innovation and technology adoption in industries characterized by network effects in final demand (e.g., Kretschmer, 20008). While these effects likely impact some of the firms in our data set, they are not the focus of our study.

This paper seeks to fill a gap in the literature by assessing the degree to which collaboration networks, as traced out by pre-existing instances of “coinvention” by inventors named in patent documents, shape the pattern of knowledge spillovers and influence the quality of individual inventions. We focus on a particular technological domain, but allow our coinvention networks to span organizational boundaries. To the best of our knowledge, we are the first to link the innovation and network literatures in this particular way.

1.2 Our Analysis and Results

In this paper, we use data on the inventors that appear in patent documents to trace out and construct a two-mode network: (I) a Patent network and (II) an Inventor network. In the case of the patent network, the nodes are patents, and two patents are linked if there are common inventors who work on both patents. In the case of the inventor network, the nodes of this network are the inventors themselves. There is a link between two inventors if they are co-inventors of the same patent. (In section 2 below we provide a simple example to distinguish these two networks.)

We examine the patent network and the inventor (collaboration) network of inventors creating technologies in the domain of information security, broadly defined. Our broad definition includes patents in ICT patent classes that the USPTO and researchers working in the field have defined as information security related classes; these are listed in detail in Appendix A and discussed later in the paper. For each patent, we calculate its proximity to other patents in the network, where the links are through inventors. We then calculate the centrality of these patents within patent network, in a manner defined below. Similarly, we calculate the centrality of inventors within the inventor network.

We then regress patent invention quality, measured by the total number of forward citations, on network centrality measures within the patent network at the time when the patent application was submitted. We control for other characteristics of the patent. We find that in the case of Israel, the network centrality measure “closeness” (which is defined below) is significantly associated with the variation in patent quality. This result provides evidence of direct and indirect knowledge spillovers propagated through inventor networks.

We use instances of the same inventors appearing together in a patent document to trace out the networks through which knowledge spillovers will be presumed to flow. Of course, this definition necessarily omits instances of collaboration or communication that are not reflected in the patent documentation “paper trail”. While acknowledging this point, we argue that unmeasured communication and interaction are likely to be highly correlated in space and time with the data that we do observe in the patent data record.

1.3 Israel's Emergence as a Global Center of Innovation in ICT/Information Security

Our primary focus is on Israel, which is recognized as one of the most innovative countries in the world. Widely cited indices of national innovative capacity, such as the Bloomberg Index of Innovation or the Global Competitiveness Index compiled by the World Economic Forum, regularly rank Israel among the world’s top 5 innovating countries, despite its small size.⁵ Reflecting this technological strength, the country has become a major global center for high-tech entrepreneurship. Excluding the U.S., only China has more firms listed on the NASDAQ stock exchange.⁶ Leading players in the global IT sector, such as Intel, IBM, Google, Motorola, Apple, Microsoft, and many others have set up research centers in Israel, hoping to harvest local talent and knowledge. Israeli companies today play a key role in shaping the global IT industry - from chips to the end user applications. Israeli firms occupy an especially prominent role in information security, which is one of the largest and fastest growing sub-sectors of ICT.

Popular explanations of Israel’s technological ascendancy characterize Israel’s size as a strength, asserting that the small nation is characterized by tightly connected networks, through which knowledge spillovers can easily flow. Elite Israel Defense Force (IDF) units, such as the well-known Unit 8200, are believed to play an important role in seeding successful startups in Israel by creating a connected network of programmers.⁷ Unit 8200, and similar units, effectively nudge a fraction of their most gifted alumni into high-tech entrepreneurship in ICT

⁵ See "The Bloomberg Innovation Index", <http://www.bloomberg.com/graphics/2015-innovative-countries/> (accessed 17/12/2016) and "Global Competitiveness Report 2015-2016 - Reports - World Economic Forum", <http://reports.weforum.org/global-competitiveness-report-2015-2016/economies/#economy=ISR> (accessed 17/12/2016.)

⁶ "Companies in Israel – Nasdaq.com", <http://www.nasdaq.com/screening/companies-by-region.aspx?region=Middle+East&country=Israel> (accessed 17/12/2016)

⁷ Unit 8200, a military intelligence unit focusing on signal intelligence and code decryption, is the largest unit in the Israel Defense Forces, comprising several thousand soldiers. It is comparable in its function to the United States' National Security Agency. See Idan Tendler, “From the Israeli Army Unit 8200 to Silicon Valley,” 23 March 2015, available at <https://techcrunch.com/2015/03/20/from-the-8200-to-silicon-valley/>

and related domains. Once they leave the military, 8200 veterans use the network of 8200 veterans to found start-ups and develop technologies based in part on their experience and connections in the military.⁸ The theme of knowledge spillovers from connected networks of former members of the military intelligence corps runs through the book *Start-Up Nation* (Senor and Singer 2009) and other sources, but no rigorous statistical study has yet confirmed that these networks have actually played an important role in the rise of Israel as a center of ICT innovation.

In this paper, we do not address the role of particular military units in fostering Israeli networks of information technology developers. However, we undertake what is, to the best of our knowledge, the first empirical effort to measure these networks, as they are traced out in patent data, and ascertain the degree to which network density affects the quality of Israeli invention. To capture information security inventions, we include all patents granted within a broad range of ICT patent classes that have been identified by the USPTO and previous researchers as containing information security patents. These classes are reasonably broad, and contain within them many patents that are not strictly information security inventions, per se. We deliberately used a broad definition, in order to be reasonably confident that we obtained all relevant inventions. Narrowly defined fields have limited numbers of patents, making econometric work more challenging. Finally, Israel is very different from the other countries because a large proportion of its patents in the ICT/Information Security sector (47 percent) are assigned to US firms. No other country with significant numbers of patents in this sector has more than 17 percent US assignees, and most of the countries have less than 5 percent or fewer US assignees.

We now briefly examine ICT/ information security patents by patent class for several countries and for the state of California, which is considered to be on the forefront of knowledge in ICT/Information Security (as well as other areas.) The percent of patents in each of the ICT/Information Security patent classes is shown in Table 1 for California, Israel, Japan, and Korea. (All tables are at the end of the paper.)

In the case of Korea, almost 60% of the patents are from categories 365 and 455. These are the two largest categories for Japan as well and account for 36% of the patents in that country.

⁸ “70 percent of successful Israeli startups are led by 8200 graduates,” says NBIC Director Fadi Swidan,” from “High-tech elites to nurture Arab-Israeli startups,” 17.4.2016, available at <http://www.israel21c.org/high-tech-elites-to-nurture-arab-israeli-startups/>

These are hardware-oriented patent classes, only parts of which are strongly related to information security. The distribution of patents across classes in Israel and California looks quite different. The percentage of patents in classes 365 and 455 are 21% and 24% respectively. Excluding class 455, which is very broad and has a large number of patents, the largest three patent classes for both Israel and California are classes 709, 711, and 714. Patent class 709 covers Electrical Computers and Digital Processing Systems: Multicomputer Data Transferring. Patent Class 711 covers Electrical Computers and Digital Processing Systems: Memory. Patent Class 714 covers Error Detection/Correction and Fault Detection/Recovery. These classes are more oriented to software than patent classes 365 (Static Information Storage and Retrieval) and Patent Class 455 (Telecommunications).

When we look at the percent of patents in the “700 classes,” less the percent of patents in the other classes containing ICT/information security patents, we see an interesting bifurcation. Israel, Canada, and California have many more patents in the “software” classes, while Korea, Taiwan, and Finland have many more patents in the hardware-oriented classes containing ICT/information security patents. Germany, France, and Japan are in the middle. See Table 2.

2. Theoretical Foundations for Network-Mediated Knowledge Spillovers

Network-mediated knowledge spillovers can be either direct or indirect. In the case of network-mediated spillovers between patented inventions, *direct* spillovers occur when two patented inventions have a common inventor who transfers knowledge from one patent to another. That is, an inventor takes the knowledge that he/she acquired while working on a previously patented invention and implements it in another invention. However, knowledge may also flow between invention teams even if they are not directly connected by a common inventor. The indirect route occurs whenever an inventor learns something from participating in one invention, takes the knowledge to a second invention and "shares" it with another inventor on that invention team, who, in turn, uses it when she works on a third invention. In such a scenario, knowledge flows from the first patent to the third patent, even though they do not have any inventors in common. Clearly, such indirect spillovers may be subject to decay depending on the distance (the number of the indirect links) between the patents.

Fershtman and Gandal (FG 2011) show theoretically that when there are project spillovers that decrease with decay, there should be a positive correlation between project success and project *closeness centrality*, which is defined as the inverse of the sum of all distances between the project and all other projects. Closeness centrality measures how far each project is from all the other projects in the network.

2.1 An Example Constructing the Patent and Inventor Networks

Before we proceed, the example below shows how to construct the patent and inventor network. Suppose that there are six inventors and five patents with the following patent-inventor data:

Patents	Inventors
Patent 1	Polly & Cindy
Patent 2	Steve
Patent 3	Thomas, Elizabeth, & Jack
Patent 4	Polly & Jack
Patent 5	Steve & Jack

The first network in Diagram 1 below shows the two-mode network with both patents and innovators. The second network shows the “Inventor Network,” where two inventors are connected if they work on a patent together. The third network is the “Patent Network.” Two patents are connected if they have an inventor in common.

In the inventor network, “Jack” is the most central and he is directly connected to all other inventors except Cindy. In the patent network, both patents 4 and 5 are directly connected to three other patents. Although patents 1 and 3 are not connected, knowledge can indirectly flow between those patents via patent 4. This is because Polly works on both patents 1 and 4, while Jack works on patents 4 and 3.

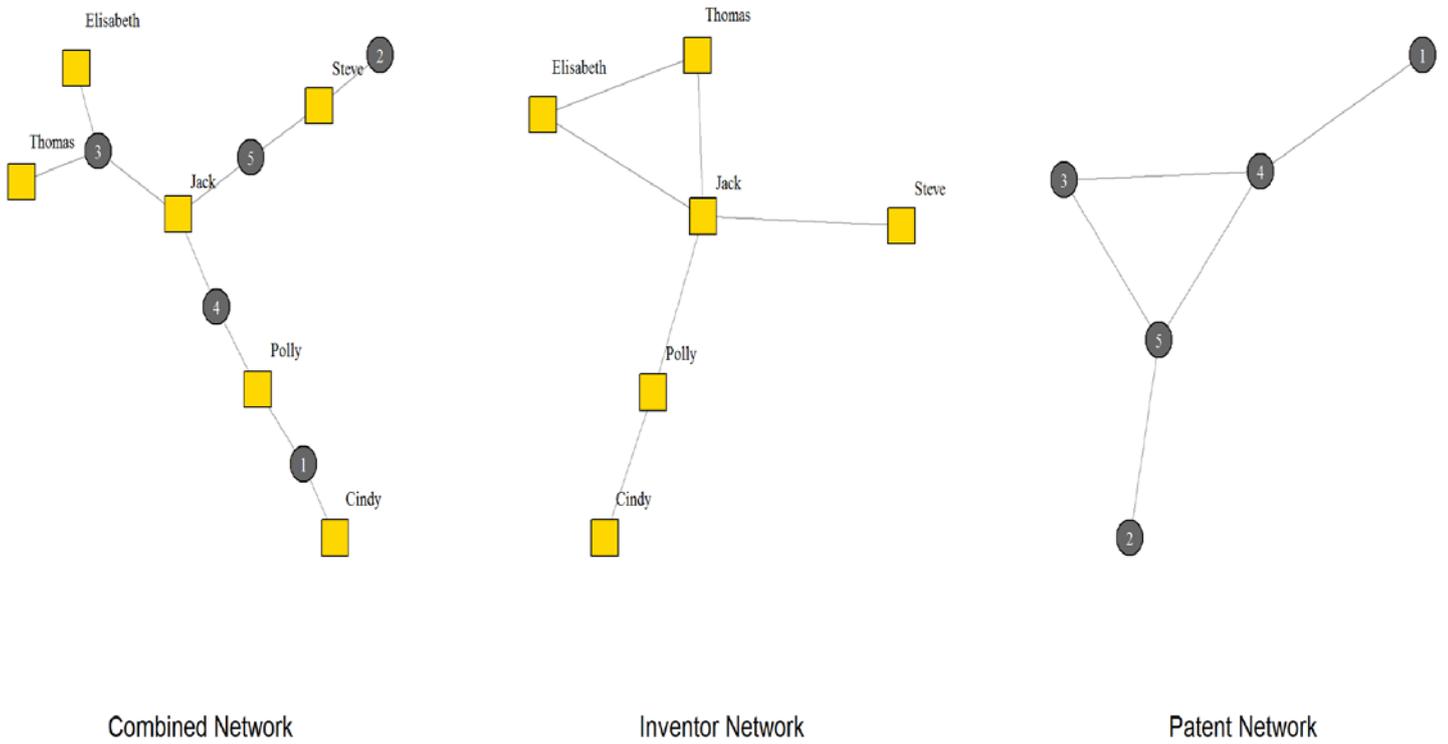

Diagram 1: A Two-mode Network and Corresponding Patent Networks

2.2 A Formal Model for Exploring Network-Mediated Knowledge Spillovers

As discussed, the academic literature has frequently used forward patent citations as a measure of invention quality. Following this convention, we assume that the quality (denoted S_i) of each patent “ i ” is closely related to its count of forward citations, i.e., the citations received from subsequently granted patents. As is typical, we exclude self-citations (both to assignees and to inventors.)

We write:

$$(1) S_i = X_i \omega + \varepsilon_i$$

where X_i is a vector of observable patent characteristics, ω is a vector of parameters to be estimated, and ε_i is an error term.

Adding Spillovers to the Model

We define two patents to be linked if they have an inventor in common. We focus on national networks. A patent is defined to be from a country if all its inventors are residents of said country, i.e., all inventors have an address in that country on a given patent document. This means, for example, that an Israeli working in the Silicon Valley lab of her multinational employer would be considered “American” for our purposes, because she is a resident of the U.S. at the time of the patent application.

There are three common measures of centrality that measure different types of spillovers: degree, closeness, and betweenness. Degree centrality measures the number of direct connections of the node (a patent in our setting.) Closeness centrality inversely measures how far the node is from all other nodes in the connected component. Betweenness centrality measures the number of shortest paths that pass through the node (patent.)

If (only) Degree centrality is significant in explaining the success of a patent, then there are direct knowledge spillovers from directly connected nodes, but no indirect spillovers.

If (only) Closeness is significant in explaining the success of a patent, then there are both direct and indirect knowledge spillovers from directly and indirectly connected nodes, and the spillovers decay with distance between the patents.

If both degree and closeness centrality are associated with success, then there are hyperbolic spillovers: (i) From closeness, there are both direct and indirect knowledge spillovers from directly and indirectly connected nodes, and the spillovers decay with distance between the patents. (ii) From degree, there is an additional spillover from a direct connection. Hence the hyperbolic effect.

If Betweenness is significant in explaining the success of a patent, then there are knowledge spillovers from being in the center of the information flow.

When we include all three measures in a regression, we find that only closeness centrality is associated with patent success. This suggests that there are both direct and indirect knowledge spillovers that decay with distance. However, there are not hyperbolic spillovers, nor are there spillovers associated with being in the center of the information flow.⁹

Given that the other measures are not associated with success, we focus on closeness centrality in the FG (2011) model we now describe. The model assumes that each patent i may enjoy positive spillovers from patents that are directly connected and patents that are indirectly connected, but that these spillovers are subject to decay that increases as the distance between the patents - that is, the number of intervening connections - in the patent network increases. Formally when the distance between patent i and j is $d(i,j)$, we assume that the quality of each patent is $\gamma/\sum_j d(i,j)$ where γ is the magnitude of the spillover.¹⁰

Under this assumption, the quality of each patent i can be written

$$(2) \quad S_i = X_i\omega + \frac{\gamma}{\sum_j d(i,j)} + \epsilon_i.$$

Formally, closeness centrality is the inverse of the sum of all the (shortest) distances between a focal patent and all other patents multiplied by the number of other patents. Closeness centrality measures how far each patent is from all the other patents in a network and is calculated as:

$$(3) \quad C_i \equiv \frac{(N-1)}{\sum_{j \in N} d(i,j)},$$

where N is the number of patents and $d(i,j)$ is the shortest distance between Israeli patents i and j , as measured by the network traced out in patent documents. Patents that indirectly link to a large number of other patents have a higher closeness centrality measure than patents near or at the edge of a network. (See Freeman (1979), pp. 225-226.)

⁹ Eigenvector centrality is another centrality measure. This measure captures the effect of nodes with influence over the whole network, not just those directly connected to it. Eigenvector centrality is in some sense a complex combination of all other centrality measures. Unlike the other centrality measures, it does not capture a particular type of spillover. In any case, when we run a regression with eigenvalue centrality, we find no significant association between this measure and success.

¹⁰ For two patents that are directly connected (that is, share an inventor in common), $d(i,j) = 1$. For two patents that are indirectly linked via a third patent, $d(i,j) = 2$.

Using (3), the expression for closeness centrality, patent i 's success can be rewritten as

$$(4) \quad S_i = X_i\omega + \gamma \frac{C_i}{N-1} + \epsilon_i$$

Hence, for each patent (denoted “ i ”), we calculate the cited patent’s “country network” closeness centrality. By construction, we only consider the possibility of *intranational* knowledge spillovers, because our networks are based on co-inventions between inventors who “meet” in the same national territory.¹¹ The closeness centrality measure is only defined within groups of patents that are actually connected to each other by common inventors. For that reason, following the usual practice in the network literature, we will focus our analysis on the largest single group of patents within Israel (and our other sample countries) that are connected to a common network. This is referred to in the literature as the “giant component.”

Endogeneity/Causality:

Importantly, we need to address the endogeneity issue associated with network formation. High quality patents will also attract large numbers of citations from subsequently granted patents. This raises the possibility that the causal linkage between network density and invention quality runs in both directions, with higher quality patents growing a denser network around them after they are invented.

To address this issue, we need to distinguish between the “ex-ante” network that was in effect when the application for the patent was filed, and the “ex-post” network that exists at the end of our data window. To do this, we create, for each patent, the coinvention network that exists at the time of the patent filing — meaning that there is a different network for each patent. Logically, this “ex ante” network is the network that could have plausibly raised the quality of the invention.¹²

¹¹ This does not imply the assumed absence of international spillovers but rather the difficulty of tracking inventor networks across countries and our interest in measuring the impact of intranational networks, especially in Israel, on invention quality. To the extent that unmeasured international collaborations raise the quality of invention, our approach is likely to generate a downward-biased estimate of the impact of Israeli inventor networks on inventions quality.

¹² Indeed, when we “incorrectly” use the “ex-post” network that at the end of our data window, rather than the “ex-ante” network in the analysis, we find that the coefficient on closeness is approximately 50% higher.

Using the “ex-ante” network helps resolve the endogeneity issue, in part because of the difficulty inventors face in forming coinvention links in a forward-looking manner. In a relatively new and fast-moving domain like information security, it can be hard to anticipate which inventors will create high quality patents in the future. The ability to form linkages is also constrained by organizational boundaries.

Perhaps more importantly, patents are generally owned by one firm, and all the inventors listed on particular patent typically work at that firm. Few inventors would choose to leave a firm just to apply for a future patent of uncertain quality with someone else at another firm. Hence, we believe our ex ante approach helps address the endogeneity issue. Casual discussions we had with insiders add support to the notion that this forward-looking strategic effect is not important in the case of patents.

An analogy may be helpful: If the same situation held in academia, i.e., researchers can only collaborate on a paper if they work for the same institution, the analogy would be as follows: Suppose researcher A wanted to write a paper with researcher B who had a position at a different University. In order to facilitate that collaboration, researcher A would have to leave his/her University and get a position at the University where researcher B works. Even if that was possible, the costs could be significant -- and would probably exceed the benefits, even if researcher B would be a good co-author.

Robustness of Results

We take a number of other steps described in more detail later in the paper to strengthen our causal inference. Importantly, we control for

- The number of inventors listed on the patent, and we directly control for this in all regressions.
- The number of backward citations since the position of a patent within the network could be related to its technological proximity to prior work.

Further, if a disproportionate number of high quality patents are (co)invented by a small number of superstar inventors, and these inventors also possess dense collaboration networks, even *ex ante*, then we could mistakenly associate the quality of these inventions with the density of the networks rather than the unique inventive capabilities of the superstar inventors. We address this by including a dummy variable for the presence of a “top 1 percent” (i.e., high-quality) inventor; our results are unchanged when we control for inventor quality.¹³

The quality of a patent is also likely to be related to the level of R&D expenditure that went into it, and, as we have noted several times, large U.S.-based multinationals are a conspicuous presence in the Israeli information security sector, collectively investing hundreds of millions of dollars in acquisitions and R&D.¹⁴ These large multinationals have created unusually large teams of well-networked inventors and provided them with unusually large amounts of money – thereby creating high quality patents whose quality could inappropriately ascribed to the density of the networks possessed by the inventors. We address this by dropping *all* patents assigned to U.S. MNCs in our sample, and our empirical results again are qualitatively unchanged.

3. Data and Empirical Analysis

3.1 Defining and Delimiting Our Patent Populations

We now turn to our empirical analysis. In order to begin, we need to define the relevant *i* patent classes. As we have already noted, from detailed examination of United States Patent and Trademark Office (USPTO) patent class descriptions and the work of prior researchers, we were able to determine the patent classes relevant for information security innovations, broadly defined. These ICT patent classes are shown in the Appendix A.¹⁵

¹³ The robustness of our results to “superstar effects” also helps guard against the possibility that unmeasured characteristics like individual “power” or status that are highly correlated with individual networks are driving our results.

¹⁴ Four large U.S.-based MNCs own more than a quarter of the patents in our sample. The role of these American acquirers is controversial, even among Israelis otherwise committed to globalization and open markets. One famous Israeli economist is known to have complained that, “Israel does not export software, it exports software companies.”

¹⁵ See <https://www.uspto.gov/web/patents/classification/uspc726/defs726.htm>, accessed 25 June 2017. We included class 709, which does not appear as a relevant patent class in the USPTO document, but according to

We then collected data from the USPTO on all patents granted in the relevant patent classes. Our data include the number of forward citations, backward citations (citations made to previously granted patents), grant year, application year, location of inventor (hence we know whether the inventor(s) are Israeli), patent class and subclass, patent title and abstract, number of inventors, and the assignee (owner) of the patent. The number of U.S. patents by country in the relevant patent classes for the years 1985-2014 is given in Table 3. Since there were relatively few information security patents before 1985, we start with that grant year. In the 1985-2014 period, the USPTO issued approximately 340,000 patents in our target patent classes in which all inventors are from the same country. The table shows that more than 50% of the patents were issued between 2005-2014.¹⁶

Because we construct the patent network (for each patent) at the time the patent was applied for, we need to have a large enough existing giant component of connected patents already in existence. A giant component formed in Israel at the end of 2006. Before that time, there were several smaller components. This is typical of network formation. In the case of Israel, this means we can include patents that were applied for beginning in 2007.

In our database, we have patents issued through 2014. Figures 1 and 2 show the formation and development of the Israeli network and its giant component over time. Complete data exist for 881 USPTO patents with Israeli inventors in this period. That is, for these patents, all inventors had an address in Israel. We exclude patents with both Israeli inventors and inventors from other countries (primarily the US) from the main analysis, since we want to focus on the local network. The number of Israeli patents is small relative to the total number of patents in the relevant classes with all inventors based in the same country. Table 4 shows that Israeli patents as a proportion of all patents granted by the USPTO in these classes increased steadily over the 1985-2014 period, but remained a small percentage of the total. The conventional wisdom regarding Israeli patents in these classes is that they stand out in terms of quality rather than quantity.¹⁷

Arora and Nandakumar (2012), should be included in the information security sector. Nothing changes if we eliminate that class.

¹⁶ Patents with missing data account for less than 5% of all patents (and 3% for Israeli patents).

¹⁷ It is also possible – and, in fact, likely – that our data include many patents that are not information security patents, strictly defined, and that the Israeli share of a more narrowly defined set of information security patents would be much higher. We chose to err on the side of being reasonably comprehensive in our definition of information security patents.

3.2 Construction of the Patent Network

We construct the network of Israeli patents by defining two patents to be linked if they have an inventor in common. Thus, we link patents via the recorded names of inventors. Although the USPTO data are reasonably thorough, the empirical literature has noted the challenges that arise in the "disambiguation" of similar names (Trajtenberg et al., 2009; Ventura, Nugent, and Fuchs, 2015; Marx, Singh, and Fleming, 2015). For the purposes of our study, we think of the use of recorded inventor names in USPTO data as raising two measurement challenges, which we refer to as "false positives" and "false negatives."

A **false positive** means that we identify a connection between two patents in the network, where this connection does not actually exist. A false positive occurs if two (or more) separate inventors have the same name. In order to reduce the potential for false positives, we drop inventors with 100 or more patents.¹⁸ Inventor names with a very large number of patents attached to them could, in fact, reflect multiple inventors, and inclusion of such inventors could lead to substantial mismeasurement. In the case of the Israeli network, we individually examined the names of all patent holders with more than 20 patents – and did not find a single case of a false positive. We are thus confident that our results are not driven by false positives in the Israeli data.

A **false negative** means we do not find a connection between two patents due to different spelling, or typing mistakes of the inventors' names. In order to reduce the probability of false negatives, we standardize all inventor names in the following ways. First, we used only lower case letters for the names. Second, we removed leading and following spaces. Third, we replaced all "-" symbols with spaces between names. Finally, we removed all punctuation symbols, such as parenthesis, commas etc. This standardization should help minimize the false negatives in our data. To the extent that they remain, and that our network omits important connects, we are underestimating the extent of the network and therefore the knowledge spillovers that may flow through them. Descriptive statistics for the Israeli network appear in Table 5.

¹⁸ We note, however, that the qualitative nature of our results is not affected whether we retain or drop inventors with more than 100 patents. There are no such inventors in the Israeli network in any case.

Israel is unique among countries in that many of its patents have US assignees. Fully 47% of the 881 Israeli patents in the giant component that were applied for beginning in 2007 have US assignees.¹⁹ For comparison, no other country has more than 17% “US Assignees” in these patent classes (applied for beginning in 2007,) and most have less than 5% US assignee patents. Hence, by this measure, Israel is “off the charts.” The high frequency of US assignees reflects the unique history of Israel’s high-tech sector. US multinationals established research, design, and production facilities in Israel at the inception of the Israeli ICT industry’s development, and have continued to play an important role. These subsidiaries were often led by Israelis returning home to Israel after years — even decades — of distinguished engineering leadership inside US-based companies. Today, many Israeli start-ups are eventually acquired by US firms, and the purchase moves ownership of Israeli patents to a U.S. entity.

3.3 Measuring Spillovers via Connected Networks

In this section, we estimate equation (4) which we repeat below:

$$(4) S_i = X_i\omega + \gamma \frac{C_i}{N-1} + \epsilon_i$$

Recall that S_i , the number of forward citations received by a given patent, is our measure of quality. We exclude self-citations and citations made by patents from the same assignee and the same inventor. We further assume that the number of forward citations received by patent i depends on a vector of observable factors, denoted X_i . These include characteristics of the patent and characteristics of the firm holding the patent (Assignee). C_i is the *closeness centrality* of patent i in the Israeli network and γ is the parameter associated closeness.

Recall that patent networks play a dual role in expanding the number of citations received by a given patent. First, existing patent networks, as measured by closeness at the time of the patent application, provide the inventors of a given patent access to useful knowledge that enhances the quality and value of invention i , and hence lead to more citations. Second, after invention i is generated, the network propagates knowledge of this useful invention (and the

¹⁹ Since the data are from the USPTO, we know whether the assignees are US or foreign entities. In the case of Israel, virtually all non-Israeli assignees are US assignees.

technical innovations it contains) to other inventor teams working on related technologies, leading to more citations over time.

Fortunately, we can disentangle these separate effects by constructing a network for each patent at the time the patent was applied for. Using the existing networks for each patent, we can estimate (4) to measure the “ex-ante” effect. Although this makes the empirical work computationally intensive, it is necessary in order to examine whether inventions benefit from the network that was in place when the patent application was filed.

Citations are highly skewed; additionally, some of the independent variables (like the number of inventors) are also highly skewed. Hence, it makes sense to use logarithms and employ the log/log specification. The term “ln” before the variable means natural log. The dependent variable used in the regressions in Table 6 is the natural log of forward citations excluding citations from the same inventor and assignee. Since some patents receive no forward citations and the natural log of zero is undefined; following a common practice in the patents literature, we will add one to the number of forward citations and take the natural log of this transformed variable.

3.4 Measuring the “Ex-Ante” Network Spillover Effect

The independent variables are the number of inventors on each patent, the number of backward citations, and closeness of the patent, where we measure closeness at the time when the patent application is filed. We control for grant year in every regression.²⁰

Column 1 in Table 6 shows the results for the Israeli patents. The estimated coefficient on closeness (γ) is positive and significant (0.17, $t=3.25^{***}$), suggesting that there are knowledge spillovers from ex-ante “connections” in the giant component. In columns 2 and 3, we repeat the analysis in column 1 for US and Israeli assignees separately. We find that the estimated coefficient on closeness (γ) is positive and significant for both groups (0.17, $t=2.08^{**}$ for Israeli assignees, coefficient=0.26, $t=4.24^{***}$ for US assignees,), again suggesting that there are

²⁰ When conducting robustness results, we also include dummy variables for patent classes. Again, our main results are unchanged: (the estimate for γ is 0.16, $t=3.09^{***}$)

knowledge spillovers from “connections” in the giant component.²¹ The estimated coefficient on backward citations is positive and significant in all cases, while the estimated coefficient on the number of innovators is significant for the full sample and for “Israeli assignees.”

Collectively, four large American firms (Apple, Google, IBM, and Intel) hold 28 percent of the “Israeli” patents in the data set. In this sense, Israel is very different from all other countries: they have very small percentages of US assignees. When we exclude patents assigned to these major firms (column 4, table 6,) the estimate of γ remains positive and highly significant (0.18, $t=2.83^{***}$), and similar to that in column 1 in Table 6. Hence, the results are not affected by excluding the very large firms from the analysis.

3.6 Robustness Analysis: Employing Characteristics from the Innovator Network

In addition to the patent network generated by connections among inventors, there is also a related inventor network. Indeed, as we noted, our data form a two-mode-network: (I) patents and (II) inventors. The two-mode-network can be partitioned into two types of nodes, e.g. patents and inventors. We can then use the two-mode network to construct two different one-mode networks: (i) the patent network and (ii) inventor network. Here we add the inventor network to the analysis, where, in the inventor network, two inventors are connected if they work together on a patent. The nodes of the inventor network are innovators and the nodes of the patent network are patents.

We include the inventor network by introducing a dummy variable that equals one for inventors who are ranked in the top one percent of all inventors in the country in terms of the number of patents the innovator holds. This dummy variable (“Super Star”) takes on the value one if the patent has a top one-percent innovator on the patent and zero otherwise. This controls for inventor quality. When constructing the “Star” variable, we make these calculations at the end of time, reflecting the notion that inventor quality is inherent. Using the top one percent is ideal because in the giant component, roughly half (about 45 percent) of the patents have such an inventor. In the Israeli patent data, 77% of the inventors have one or two patents, while 10% have more than five patents.

²¹ The coefficient for American assignees seems significantly larger than that of Israeli assignees, but the differences are not statistically significant.

It is interesting to examine whether (controlling for network structure) such “stars” affect the success of the patent. We find that in the case of Israel, beyond the effect it has on the network, the presence of such stars does not affect the success of the patent. The coefficient of a dummy variable signifying the existence of a top 1% inventor on the inventor team of a patents is quite small and statistically insignificant. (The coefficient estimate is only -0.004, and t-statistic is -0.11.) The estimate of γ is unaffected by inclusion of this variable. The estimated coefficient on γ remains positive and statistically significant (0.17, $t=3.16^{***}$). See column 5, table 6. These results suggest that our measure of closeness centrality is not merely a proxy for the presence on the inventor team of highly accomplished individual inventors. Instead, they are fully consistent with the view that much of what makes highly accomplished inventors valuable members of a research team is the knowledge spillovers — direct and indirect — that they bring into a research collaboration.

4. Brief Conclusions

For nearly a quarter century, researchers have used patent citation data to trace out knowledge spillovers across inventions, organizations, and regions. From the inception of this literature, researchers have recognized the potential importance of direct interaction between inventors, but relatively few studies have sought to measure inventor networks explicitly, and fewer still have sought to quantify the degree to which these networks function as mechanisms for the transmission of knowledge spillovers.

Drawing inspiration from related work on open source software projects, this study seeks to advance the literature by using the pattern of inventor interaction traced out in patent documents to create measures of inventor networks; we go on to empirically measure the association between the location of a patent within this network and the quality of invention as measured by forward citations. We apply these techniques in an interesting context – ICT/ information security technology in Israel. This is a domain in which Israeli inventors have recently emerged as globally important creators of new technology. Industry accounts suggest that the rapid rise of Israeli firms to this position of global prominence has been driven, in part, by the unusually strong networks that characterize Israeli inventors operating in this domain. These networks are believed to help produce better inventions, and then rapidly convey the new technologies embodied in these inventions to subsequent inventor teams. Despite wide acceptance of this

conventional wisdom, no empirical research has yet convincingly related Israeli invention quality to Israeli inventor networks. This paper presents empirical evidence supporting and extending this conventional wisdom. We find that the quality of Israeli ICT inventions is systematically related to the location of these patents within the Israeli invention network.

(2) Financial Technology (Fin-Tech)

(3) Medical Technology (Med-Tech)

These are all areas of innovation that require computer science expertise and programming skills, areas in which Israel should have a comparative advantage. In the analysis, we use data from the United States Patent and Trademark Office (USPTO.)

Using the theoretical model we present, we then regress patent invention quality, measured by the total number of forward citations, on network centrality measures within the patent network at the time when the patent application was submitted. We control for other characteristics of the patent.

We find that the quality of the Israeli ICT/information security inventions is systematically linked to the structure of the collaborative network. In particular, we find positive and significant direct and indirect knowledge spillovers. Further, the spillovers are stronger when we restrict ourselves to patents in the narrow IS/ICT network, that is patents that do not also fall into Med-Tech or Fin-Tech. We find no evidence of spillovers in either Fin-Tech or Med-Tech.

One possible explanation for our results is that the connected networks formed in Elite Israel Defense Force (IDF) units, such as the well-known Unit 8200, play an important role in seeding successful ICT/IS startups in Israel by creating a connected network of programmers. Unit 8200, a military intelligence unit focusing on signal intelligence and code decryption, is the largest unit in the Israel Defense Forces, comprising several thousand soldiers.²² Once they leave the military, 8200 veterans use the network of 8200 veterans to found start-ups and

develop ICT/IS technologies based in part on their experience and connections in the military.²³ Such effects are not likely present in the Med-tech and Fin-tech categories.

	# of All Patents	# of Israeli Patents	% of Israeli Patents
1985 - 1989	11253	32	0.28%
1990 - 1994	16417	71	0.43%
1995 - 1999	36492	256	0.70%
2000 - 2004	54745	554	1.01%
2005 - 2009	82732	980	1.18%
2010 - 2014	137889	2538	1.84%
Total	339528	4431	1.31%

Table 5: Descriptive Statistics - Israel

	N	Mean	Std. Dev	Minimum	Maximum
Forward Citations	881	1.70	6.05	0	66
Forward Citations â€œNo self citationsâ€	881	1.42	5.74	0	64
Grant Year	881	2012.62	1.36	2008	2014
Application Year	881	2009.78	1.83	2007	2014
# of inventors	881	2.75	1.49	1	11
Backward Citations	881	36.15	82.85	0	547
US Assignee	881	0.47	0.50	0	1
Closeness/(N-1)	881	0.000105	0.000051	0.000034	0.000236

Note: The table presents descriptive statistics for all the Israeli patents that are in the Israeli Giant component in 2014, and were applied between 2007 and 2014. Forward citations include the number of citations a patent receives. Forward citations “No self cites”, includes all the citations a patent receives, excluding citation made by patents from the same inventors or the same assignee. Grant year is the year the patent was approved by the USPTO. Number of inventors are the number of inventors listed as the patent inventors. Closeness is the patent closeness centrality measure, in the patent network formed until the patent application year. Backward citations are the number of patents that were cited by the patent. US Assignee is an indicator variable that indicates whether the patent was applied by a US assignee. We identify a patent as one that was originated in Israel if all its inventors home addresses were listed under Israel, according the USPTO data.

Table 6: Regressions - Israel

	(1)	(2)	(3)	(4)	(5)
	Overall	US Assignees	Israeli Assignees	Without Major Firms	With Superstar
ln(Closeness)	0.171*** (0.053)	0.263*** (0.062)	0.173** (0.083)	0.177*** (0.061)	0.172*** (0.055)
ln(# of Inventors)	0.069* (0.037)	0.015 (0.039)	0.148** (0.063)	0.066 (0.047)	0.069* (0.037)
ln(Backward Cites)	0.092*** (0.015)	0.035** (0.016)	0.141*** (0.026)	0.111*** (0.020)	0.093*** (0.016)
SuperStar					-0.005 (0.044)
N	881	416	464	681	881
Adj. R^2	0.367	0.302	0.361	0.375	0.367
Grant Year Dummies	Yes	Yes	Yes	Yes	Yes

Note: The dependent variable is the natural log of one plus the number of forward citations. While counting forward citations, we exclude citations made by the patent's inventors other patents, and citations made by other patents that are listed under the patent's assignee. Number of inventors is the number of inventors listed in the USPTO data. Backward Cites is one plus the number of citations made by the patent. Closeness is the closeness centrality measure the patent have in the relevant Israeli patent network. In column (1) we regress on all Israeli patents applied for after 2007 and we define the Closeness of a patent by looking at the network that existed up until the patent application year. In column (2) we regress the same specification on patents with US Assignees. In column (3) we repeat the regression for patents with non-US assignees. In column (4) we omit patents that were applied by IBM, Apple, Google and Microsoft and in column (5) we control for "Super Stars". Standard error are in parenthesis. =significant at 10% level, **=significant at 5% level, ***=significant at 1% level.

Appendix A: Relevant Patent Classes for Information Security:¹

- 326,** Electronic Digital Logic Circuitry, subclass **8** for digital logic circuits acting to disable or prevent access to stored data or designated integrated circuit structure.
- 340,** Communications: Electrical, subclasses **5.2** through **5.74**, for authorization control without significant data process features claimed, particularly subclasses 5.22-5.25 for programmable or code learning authorization control; and subclasses 5.8-5.86 for intelligence comparison for authentication.
- 365,** Static Information Storage and Retrieval, subclass **185.04** for floating gate memory device having ability for securing data signal from being erased from memory cells.
- 380,** Cryptography, subclasses **200** through **242** for video with data encryption; subclasses 243-246 for facsimile encryption; subclasses 247-250 for cellular telephone cryptographic authentication; subclass 251 for electronic game using cryptography; subclasses 255-276 for communication using cryptography; subclasses 277-47 for key management; and subclasses 287-53 for electrical signal modification with digital signal handling.
- 455,** Telecommunications, subclass **410** for security or fraud prevention in a radiotelephone system.
- 704,** Data Processing: Speech Signal Processing, Linguistics, Language Translation, and Audio Compression/Decompression, subclass **273** for an application of speech processing in a security system.
- 705,** Data Processing: Financial, Business Practice, Management, or Cost/Price Determination, subclass **18** for security in an electronic cash register or point of sale terminal having password entry mode, and subclass 44 for authorization or authentication in a credit transaction or loan processing system.
- 708,** Electrical Computers: Arithmetic Processing And Calculating, subclass **135** for electrical digital calculating computer with specialized input for security.
- 709,** Electrical Computers and Digital Processing Systems: Multicomputer Data Transferring, subclass 225 for controlling which of plural computers may transfer data via a communications medium.
- 710,** Electrical Computers and Digital Data Processing Systems: Input/Output, subclasses **36** through **51** for regulating access of peripherals to computers or vice-versa; subclasses 107-125 for regulating access of processors or memories to a bus; and subclasses 200-240 for general purpose access regulating and arbitration.
- 711,** Electrical Computers and Digital Processing Systems: Memory, subclass **150** for regulating access to shared memories, subclasses 163-164 for preventing unauthorized memory access requests.
- 713,** Electrical Computers and Digital Processing Systems: Support, subclasses **150** through **181** for multiple computer communication using cryptography; subclasses 182-186 for system access control based on user identification by cryptography; subclass 187 for computer program modification detection by cryptography; subclass 188 for computer virus detection by cryptography; and subclasses 189-194 for data processing protection using cryptography.
- 714,** Error Detection/Correction and Fault Detection/Recovery, subclasses **1** through **57** for recovering from, locating, or detecting a system fault caused by malicious or unauthorized access (e.g., by virus, etc.).
- 726** Protection of data processing systems, apparatus, and methods as well as protection of information and services.
